A Study of <i>The Behavior of Law</i> Michael R. Gottfredson and Michael J. Hindelang	3
Comment: Common Sense in the Sociology of Law Donald Black	18
Response: Theory and Research in the Sociology of Law Michael R. Gottfredson and Michael J. Hindelang	27
Class as Conceived by Marx and Dahrendorf Robert V. Robinson and Jonathan Kelley	38
Overcrowding in the Home Walter R. Gove, Michael Hughes, and Omar R. Galle	59
Toward a Class-Dialectical Model of Power J. Allen Whitt	81
Paradigms in Evolutionary Theory Jill S. Quadagno	100
Size and Administrative Intensity in Nations Patrick D. Nolan	110
Possible Causes of the Apparent Sex Differences in Physical Health Walter Gove and Michael Hughes	126
Decision Making and Non-Decision Making in Cities Richard A. Smith	147
Comments Gail Landsman, Steven Stack, Walter L. Goldfrank, John W. Heeren, and Christopher B. Norton	162

Notice to Contributors

A processing fee of \$10 is required for each paper submitted, including comments; such fees will be waived for student members of ASA. A check or money order, made payable to the American Sociological Association, should accompany each submission. The fee must be paid in order for the review process to begin.

The maximum length of an *ASR* paper is typically ten (10) printed pages or thirty (30) typed manuscript pages including space for tables, figures and references. Due to space limitations, we must request contributors to conform to this norm as closely as possible.

To permit anonymity in the review of manuscripts, keep identifying material out of the manuscript. Attach a cover page giving authorship, institutional affiliation and acknowledgments, and provide only the title as identification on the manuscript and abstract.

ASA Multiple Submissions Policy: Submission of a manuscript to a professional journal clearly implies commitment to publish in that journal. The competition for journal space requires a great deal of time and effort on the part of editorial readers whose main compensation for this service is the opportunity to read papers prior to publication and the gratification associated with discharge of professional obligation. For these reasons, *the American Sociological Association regards submission of a manuscript to a professional journal while that paper is under review by another journal as unacceptable.*

SUBMISSION AND PREPARATION OF MANUSCRIPTS

1. Submit four (4) copies and retain the original for your files. Copies may be Xerox, mimeograph or multilith, but not carbons.
2. Enclose a stamped self-addressed postcard for acknowledgment of manuscript receipt. *Manuscripts will not be returned.* Please do not send your original copy.
3. All copy must be typed, doublespaced (including indented material, footnotes and references) on 8½ by 11 inch white opaque paper. Lines must not exceed six (6) inches. Margins must be a minimum of one inch.
4. Include four (4) copies of an abstract of no more than 150 words.
5. Type each table on a separate page. Insert a location note at the appropriate place in the text, e.g., "Table 2 about here." Send copies, retain originals.
6. Figures must be drawn in India ink on white paper. Send copies, retain originals.
7. Clarify all symbols with notes in the margins of the manuscript. Circle these and all other explanatory notes not intended for printing.
8. Footnotes should not be placed in the body of the text. Type them (doublespaced) and attach them as a separate appendix to the text. Number them consecutively throughout the text. Footnotes are to be kept to a minimum and used only for substantive observations. Source citations are made within the text rather than in footnotes.
9. Acknowledgments, credits and grant numbers are placed on the title page with an asterisk.

REFERENCE FORMAT

A. *In the text:* All source references are to be identified at the appropriate point in the text by the last name of the author, year of publication and pagination where needed. Identify subsequent citations of the same source in the same way as the first, not using "*ibid.*," "*op.cit.*," or "*loc. cit.*" Examples follow:

1. If author's name is in the text, follow it with year in parentheses. ["... Duncan (1959) ..."]
2. If author's name is not in the text, insert, in parentheses, the last name and year, separated by a comma. ["... (cf. Gouldner, 1963) ..."]
3. Pagination (without "p." or "pp.") follows year of publication after a colon. ["... Kuhn (1970:71)."]
4. Give both last names for dual authors; for more than two use "et al." in the text. When two authors have the same last name, use identifying initials in the text. For institutional authorship, supply minimum identification from the beginning of the complete citation. ["... (U.S. Bureau of the Census, 1963:117) ..."]
5. Separate a series of references with semicolons and enclose them within a single pair of parentheses. ["... (Burgess, 1968; Marwell et al., 1971; Cohen, 1962) ..."]

B. *In the appendix:* List all source citations by author, and within author by year of publication, in an appendix titled "References." The reference appendix must be complete and include all references in the text. The use of "et al." is not acceptable in the appendix; list the names of all authors. (See A. 4. for text format.)

If there is more than one reference to the same author and year, distinguish them by the letters, a, b, etc. added to the year. ["... Levy (1965a:331) ..."] Give the publisher's name in as brief a form as is fully intelligible. For example, John A. Wiley and Sons should be "Wiley." If the cited material is unpublished, use "forthcoming" with name of journal or publisher; otherwise use "unpublished."

Use no underlining, italics or abbreviations.

Examples follow:

1. **Books:** Jud, Gerald J., Edgar W. Mills, Jr. and Genevieve Walters Burch
1970 *Ex-Pastors*. Philadelphia: Pilgrim Press.
U.S. Bureau of the Census
1960 *Characteristics of Population*. Volume 1. Washington, D.C.: U.S. Government Printing Office.
Bernard, Claude
[1865] *An Introduction to the Study of Experimental Medicine*. Tr. Henry Copley Greene. New York: Dover.
1957
2. **Periodicals:** Conger, Rand
Forth- "The effects of positive feedback on direction and amount of verbal-
coming zation in a social setting." *Pacific Sociological Review*.
Merton, Robert K.
1963a "The ambivalence of scientists." *Bulletin of The Johns Hopkins Hospital* 112:77-97.
1963b "Resistance to the systematic study of multiple discoveries in science." *European Journal of Sociology* 4:237-82.
3. **Collections:** Davie, M.
1938 "The pattern of urban growth." Pp. 133-61 in G. Murdock (ed.), *Studies in the Science of Society*. New Haven: Yale University Press.

See recent issues for further examples.

Editor: RITA J. SIMON

Deputy Editors: CLARK MCPHAIL AND ROSS M. STOLZENBERG

Associate Editors: MICHAEL T. AIKEN, ROBERT EVAN COLE, BEVERLY DUNCAN, BERNARD FARBER, DANIEL GLASER, MICHAEL HINDELANG, GISELA J. HINKLE, ROSABETH KANTER, JAMES R. KLUEGEL, BARBARA LASLETT, JOHN LOFLAND, MURRAY MELBIN, ANTHONY OBERSCHALL, VALERIE K. OPPENHEIMER, SAMUEL PRESTON, ALEJANDRO PORTES, BARBARA RESKIN, RICHARD RUBINSON, BARBARA SOBIESZEK, DAVID SNYDER, JOHN WILSON, MAYER ZALD

Copy Editor: MARY S. MANDER

Managing Editor: LINNA MCDADE

Editorial Assistant: CLYDENE MORGAN

Executive Officer: RUSSELL R. DYNES

SCOPE AND MISSION OF AMERICAN SOCIOLOGICAL REVIEW: The *American Sociological Review* publishes work of interest to the discipline in general, new theoretical developments, results of research that advances our understanding of the most fundamental social processes, and important methodological innovations. Like other publications of the Association, emphasis is given to exceptional quality. Unlike the more specialized journals of the Association, the *American Sociological Review's* primary focus is on what-ever has the most general bearing on the knowledge of society.

Concerning manuscripts, address: Editor, *American Sociological Review*, Department of Sociology, University of Illinois, Urbana, Illinois 61801. (217) 333-6515.

The *American Sociological Review* (ISSN 0003-1224) is published at 49 Sheridan Avenue, Albany, New York, bimonthly in February, April, June, August, October, and December.

Applications for permission to quote from this journal should be addressed to the Executive Office.

Copyright © 1979 American Sociological Association.

Annual membership dues of the Association: Member and International Member, \$30-50; Student Member, \$15; Associate, \$20; Student Associate, \$10; International Associate, \$12.

Application for membership and payment of dues should be made to the Executive Office. Subscription rate for members, \$10; nonmembers, \$15; institutions and libraries, \$30; nonmember students, \$10. Single issue, \$4.

New subscriptions and renewals will be entered on a calendar year basis only.

Change of address: Six weeks advance notice to the Executive Office and old address as well as new are necessary for change of subscriber's address.

Concerning advertising, changes of address, and subscriptions, address: Executive Office, American Sociological Association, 1722 N Street, N.W., Washington, D.C. 20036.

Claims for undelivered copies must be made within the month following the regular month of publication. The publishers will supply the missing copies when losses have been sustained in transit and when the reserve stock will permit.

Second class postage paid at Washington, D.C. and additional mailing offices.

New Policy

- Starting as soon as possible, the ASR will introduce a Research Notes and Reports Section. We will be interested in receiving manuscripts that fit those qualifications.
- On the regular articles, we are loosening our page limitations somewhat, and would be happy to review manuscripts that are up to fifty manuscript pages.

ITEMS

- MICHAEL R. GOTTFREDSON (A Study of the Behavior of Law; Response: Theory and Research in

the Sociology of Law) is Director of the Criminal Justice Research Center, Albany, and Visiting Assistant Professor in the School of Criminal Justice, State University of New York at Albany. His re-

ITEMS

■ PATRICIA MADOO LENGERMANN (The Founding of the *American Sociological Review*) is Professor of Sociology at George Washington University. She is currently doing research on the Chicago School and its influence on the profession.

■ GLENN FIREBAUGH (Structural Determinants of Urbanization in Asia and Latin America) is Assistant Professor in the Department of Sociology at Vanderbilt University. He is studying the linkages between agriculture and fertility in Third World countries. He is particularly interested in the effect of agricultural density on fertility.

■ IRVING TALLMAN (Values, Distributive Justice and Social Change) is Professor and Chairman in the Department of Sociology at Washington State University. He is author of *Passion, Action and Politics: A Perspective on Social Problems and Social Problem Solving* (Freeman, 1976). He is completing a cross-national study of "Socialization for Social Change" based on data gathered in Mexico and the United States. MARILYN IHINGER-TALLMAN is Assistant Professor in the Department of Sociology at Washington State University. She is beginning a research project on value socialization and sex differences.

AMERICAN SOCIOLOGICAL REVIEW

A STUDY OF *THE BEHAVIOR OF LAW**

MICHAEL R. GOTTFREDSON

State University of New York, Albany

MICHAEL J. HINDELANG

State University of New York, Albany

American Sociological Review 1979, Vol. 44 (February):3-18

In *The Behavior of Law*, Black (1976) sets forth a theory of law that he argues explains variations in law across societies and among individuals within societies. Black argues that law can be conceived of as a quantitative variable, measured by the number and scope of prohibitions, obligations and other standards to which people are subject. Law varies, according to Black, with other aspects of social life, including stratification, morphology, culture, organization, and social control. Many of Black's principal propositions regarding the quantity of law are tested in this paper with National Crime Survey data on the victim's decision to report a crime to the police. An alternative model that views the quantity of law as depending largely on the gravity of the infraction against legal norms is posed and tested against Black's theory. The data are generally inconsistent with the propositions derived from *The Behavior of Law* and strongly suggest that a theory attempting to explain the criminal law cannot ignore the gravity of the infraction against legal norms.

Introduction

The Behavior of Law (Black, 1976) has been referred to as a "crashing classic" (Nader, n.d.) and the most important contribution ever made to the sociology of law—"that and more" (Sherman, 1978). Although Black's theory has also been criticized as "circular" (Michaels, 1978), it is apparent that it will be the stimulus for a great deal of research in coming years. This is so because Black's theory of law is stated in explicit propositional form and because he sees the theory as applying to so many aspects of law (e.g., both criminal and civil) and at so many levels of analysis (e.g., individual level, community level, and societal level).

Black defines law as "governmental social control" (1976:2) and argues that law is a quantitative variable that varies across time and space as well as across characteristics of individuals:

... the quantity of law is known by the number and scope of prohibitions, obli-

tions, and other standards to which people are subject, and by the rate of legislation, litigation, and adjudication. . . . Any initiation, invocation, or application of law increases its quantity. . . . (1976:3)

According to Black, the quantity of law varies with other aspects of social life: stratification, morphology, culture, organization, and social control. In connection with each of these dimensions Black sets forth a series of propositions that he argues explain variations in law across societies and among individuals within a given society (1976:6-7).¹ For example, "law varies directly with rank [e.g., income]. . . . People with less wealth have less law. They are less likely to call upon the law in dealing with one another" (1976:17). In this paper we will examine many of Black's propositions, empirically test their predictions, and discuss the implications for the sociology of criminal law.

* Address all communications to: Michael R. Gottfredson; Criminal Justice Research Center; One Alton Road; Albany, NY 12203.

¹ Black discusses "styles of law" as well as quantity of law. The styles include penal, compensatory, therapeutic and conciliatory (Black, 1976:4-5). Because of the nature of our data, we will limit our discussion to penal (criminal) law.

The task that Black (1976:7) sets for himself is to illustrate a strategy for the construction of sociological theory that "... predicts and explains social life without regard to the individual as such. It neither assumes nor implies that he is, for instance, rational, goal-directed, pleasure seeking, or pain avoiding." Black is particularly concerned about avoiding explanations that rely on individual *motivation*. For example, he argues repeatedly that both the theory of law and "the theory of illegal behavior" explain the same facts (e.g., the crime rate).

The theory of illegal behavior, however, explains these facts with the principles that motivate an individual to violate the law. . . . The theory of law predicts the same facts, but as an aspect of the behavior of law, not of the motivation of the individual. (Black, 1976:9)

As a consequence of this macrotheoretical approach, Black is careful to avoid explanations or propositions that rely directly upon variations in the behavior of individuals. He argues that the behavior of law, *in all respects*, can be explained by social structural variations and by the relative social structural positions of the actors (e.g., the victim and the offender), without reference to how the nature of individual behavior affects the behavior of law.

One of the major difficulties facing those who would test Black's theory of law is that he is not explicit about how the objective seriousness of the offense should be handled. Contrary to the traditional sociological use of the term *seriousness*, as incorporating the consequences of acts to individuals, such as bodily injury or financial loss (see Sellin and Wolfgang, 1964), Black defines the seriousness of infractions by the amount of law that they evoke. Thus, Black argues that "[i]f a poor man commits a crime against another poor man, for example, this is less serious than if both are wealthy. Less happens . . .," and that "the more organized the victim of a crime, for instance, the more serious is the offense" (Black, 1976:17,95). For Black (1976:9), "... the seriousness of deviant behavior is defined by the quantity of law to which it is subject." What this implies,

therefore, is that Black's entire theoretical framework is designed to account for the quantity of law without including the consequences of the deviance to the victim as a dimension of the theory. This is so because the quantity of law is Black's dependent variable—a quantity that varies as a function of stratification, morphology, culture, organization, and (nonlegal) social control—and, thus, "seriousness" is not defined apart from the dependent variable itself. Hence, Black does not use seriousness in its traditional sense to *explain* variations in the quantity of law. None of the formal propositions presented incorporates harm to the victim as a consideration, and never is variation in litigation, arrest, prosecution, or sentencing accounted for by Black in terms of variation in *conduct*.

Although Black frequently uses such phrases as "all else constant" (e.g., Black, 1976:28,47,114) when stating a theoretical proposition, such qualifications can reasonably apply only to variables included in the theory. If "all else constant" can refer to variables not incorporated by the theory then the theory must be rejected as untestable. If "all else" is limited to dimensions and propositions formally specified by Black, then the consequences of legal infractions to individuals must be considered by Black to be irrelevant in accounting for the quantity of law. For example, in connection with his stratification propositions, Black (1976:31) notes "... that these principles apply whatever the actual behavior of the lower ranks—whether, for example, it is more or less violent or predatory—since their conduct is more likely to be defined as illegal no matter what they do." On the basis of such statements and the context within which Black discusses his theory of law, he must be interpreted as arguing that the *individual* consequences of legal infractions, such things as injury and monetary loss, are not an important consideration in explaining the behavior of law. At a minimum, he must be interpreted as arguing that the individual consequences of legal infractions, such as harm to victims of crimes (seriousness of the offense in its conventional use), are less important than stratification, morphology, culture, orga-

nization, and social control in determining the behavior of law. An alternative to Black's theory of law, therefore, is one that explains the behavior of law as a function of the individual consequences of legal infractions (such as harm to the victim) rather than as a function of Black's five dimensions (and their associated propositions). Our alternative model is simply that the behavior of criminal law depends primarily on what happens between the victim and the offender; the extent of harm suffered is the principal determinant of the quantity of law.

The Data

Many of the propositions set forth by Black can be tested using data available from the National Crime Survey (NCS) conducted by the Bureau of the Census for the Law Enforcement Assistance Administration. Because the methods and procedures used in these victimization surveys have been discussed in detail elsewhere (U.S. Bureau of the Census, 1975; Hindelang et al., 1978), they will be described only briefly here.

In these surveys, multistage cluster sampling is used to select representative samples of Americans twelve years of age or older in order to ask them about common assault and theft victimizations that they may have suffered during the six months preceding the interview. In this design about 130,000 persons are interviewed twice per year. The data used here are for crimes reported as having occurred during 1974, 1975, or 1976. This paper is limited to personal crimes in which there was some actual contact between the victim and the offender—rape, robbery, assault, and personal larceny (e.g., purse snatch). Because of the complex sampling design, data *weighted* to yield valid national estimates are used here. For these years the mean weight is about 1,000.²

The victimization survey data are particularly well-suited to testing many of Black's propositions because he explicitly frames much of his discussion in terms of

criminal law examples, such as complaints to the police, arrests, and prosecutions. The victimization survey data not only contain the requisite information Black discusses about the victim (e.g., social rank) and the offender (e.g., number of offenders) but also contain the information necessary to assess a variety of ecological propositions set forth by Black. Furthermore, one of the principal measures of the quantity of law discussed by Black (1976:3) is complaint to the police:

A complaint to a legal official, for example, is more law than no complaint, whether it is a call to the police, a visit to a regulatory agency, or a lawsuit. Each is an increase in the quantity of law.

For the crimes of common theft and assault, initiation of the criminal justice process is almost exclusively in the hands of the victim (Reiss, 1971; Hindelang and Gottfredson, 1976). Because victimization data include both crimes reported to the police and crimes not reported to the police, they permit an empirical assessment of many of Black's propositions regarding *initiation* of the criminal law. Consequently, most of this paper will center on Black's propositions within the context of the victim's decision about reporting the offense to the police. With the victimization survey data it is possible to assess propositions relating to each of Black's five major dimensions. The first of these is stratification.

Stratification

Black (1976:11) defines stratification as the "vertical aspect of social life," the "uneven distribution of the material conditions of existence, such as food and shelter, and the means by which these are produced, such as land, raw materials, tools, domestic animals, and slaves." According to Black, the quantity of law varies directly with social rank, and downward law (e.g., a complaint by a wealthier man against a poorer man) is more likely than upward law:

In the case of a crime, for instance, a victim who is above the offender in rank is more likely to call the police than a victim whose rank is lower than the offender's Hold

² The weights reflect the inverse of the probability of selection, adjusted for within-strata nonresponse, among other factors. See U.S. Bureau of the Census (1975) for details.

constant the offender's rank and wealthier people complain more about everything. In criminal matters, for instance, the likelihood of a call to the police increases with the rank of the victim. (1976:21, 27)

With the victimization survey data it is possible to test this proposition by examining the extent to which reporting crimes to the police varies as a function of the social rank of the victim. Most research literature indicates that offenders in crimes of *common theft and assault* are drawn disproportionately from lower ranks. Because Black (1976:31, 30) stipulates these findings ("... criminality varies inversely with rank . . ."), from his stipulation and his proposition it follows that the proportion of victims reporting their victimizations to the police will increase with the victim's rank. Table 1 shows the relationship between the victim's family income (Black's principal indicator of social rank) and proportionate reporting of victimizations to the police.³

In order to examine the effects of harm to the victim on reporting to the police, the data in Table 1 are tabulated also by seriousness level as measured by the Sellin-Wolfgang (1964) seriousness scale. This seriousness scoring system was developed using a magnitude estimation procedure and it is designed to take into account the extent and nature of bodily injury, weapon use, intimidation, forcible sexual intercourse, and financial loss.⁴

³ Victims were asked whether "the police were informed of this incident in any way?" Those responding "no" or "don't know" were classified as "no" for the purpose of this paper. "Yes" included victimizations reported to the police by the victim or someone in the victim's household, victimizations reported by "someone else" and victimizations in which the "police [were] on the scene." Virtually all of the "yes" responses (95%) involved reports to the police.

⁴ According to this method elements of the victimization are scored for seriousness resulting in seriousness scores that range from zero to 26. A victimization resulting in a score of zero would be an attempted crime in which no injury or loss was suffered and in which no weapon was used. A score of 26 is indicative of a homicide, although homicide is not among the crimes counted in the survey. Victimization events are concentrated among the lower seriousness scores (Hindelang, 1976: Chap. 6). In order to have a sufficient number of (unweighted) victimizations, four seriousness levels were used: level 1 = 0 and 1; level 2 = 2 and 3; level 3 = 4 and 5; and level 4 = 6 or more.

Table 1 shows a substantial seriousness effect; as the gravity of the victimization increases so too does reporting to the police. Contrary to Black's hypothesis, however, there is little systematic variability in rates of reporting to the police, as a function of income. Collapsing across seriousness level, the gamma for Table 1 between reporting to the police and family income is $-.017$; within seriousness levels the gammas range from $-.037$ to $.110$. On the other hand, the gamma for the relationship between reporting and seriousness level (collapsing across income) is $.305$. This effect is of similar magnitude within income categories (gammas range from $.260$ to $.453$). Clearly, Table 1 is not consistent with Black's stratification postulate.

One need not accept the stipulation made by Black regarding the inverse relationship between criminality and rank in order to assess Black's stratification postulate with these data. A corollary to the proposition tested above is that people with less wealth are "less likely to call upon law in their dealings with one another . . ." (1976:17). What this implies, then, is that victimizations between persons known to each other (and, hence, likely to be similar in social rank) are more likely to be reported to the police by persons of higher rank than by persons of lower rank. Respondents in the survey were asked whether the offender was someone known to them (a relative, a good friend, or a casual acquaintance) or was a stranger. The data presented in Table 1 were analyzed separately for crimes involving persons reported by victims to be nonstrangers. The results for crimes between nonstrangers, shown in Table 2, are parallel to those shown in Table 1. For nonstranger victimizations only, collapsing across seriousness, the gamma between income and reporting to the police is equal to $-.102$; within seriousness levels gammas ranged from $-.110$ to $.050$. Thus, Black's prediction that people with less wealth are less likely to call upon law in their dealings with one another does not find support in these data.

Another stratification hypothesis put forth by Black (1976:15) is that wherever people are more equal there is less law:

Table 1. Proportion of Victimization^a Reported to the Police, by Seriousness Level and Family Income, United States, 1974-1976^b

Seriousness level	Family Income						Total	Gamma ^c
	Under \$3,000	\$3,000-7,499	\$7,500-9,999	\$10,000-14,999	\$15,000-24,999	\$25,000 or over		
1	37% (597,981)	38% (1,074,219)	42% (536,633)	39% (1,020,397)	39% (884,764)	24% (314,841)	38% (4,428,835)	-.037
2	38% (911,012)	40% (1,613,392)	41% (784,072)	41% (1,551,184)	36% (1,360,122)	37% (520,612)	39% (6,740,394)	-.022
3	45% (648,790)	52% (1,371,611)	54% (601,848)	57% (1,201,633)	54% (925,056)	56% (276,855)	53% (5,025,793)	.076

^a Includes rape, robbery, assault, and personal larceny.

^b Numbers in parenthesis are the weighted counts which serve as the base of the percentages.

^c Each gamma was computed from a 2x6 table (reported vs. not reported by income level). For example, the gamma listed for seriousness level one reflects the relationship between reporting to the police and income level, with level of seriousness controlled. The gamma listed for the Total row reflects the relationship between reporting to the police and income level irrespective of seriousness level.

"there is less law among neighbors, colleagues, [and] friends. . . ." Table 2 also presents data useful in assessing this proposition. Black's theory predicts that crimes between strangers are more likely than crimes between nonstrangers to be reported to the police. An examination of the percentage differences in proportions reporting to the police crimes committed by strangers vs. crimes committed by nonstrangers for the cells of Table 2 reveals a mean difference of only 4% in the direction predicted by Black.⁵

In addition to stratification effects at the individual level, Black's theory of law is equally applicable to variations in law across aggregates. In relation to stratification:

It is even possible to rank entire societies among themselves, and also the areas of society, its regions, communities, and

neighborhoods. This may be done either according to the distribution of wealth among the residents or according to the wealth of the society or area itself. In the first case, law varies with the proportion of the population that is more or less wealthy. (Black, 1976:20)

By categorizing respondents in the sample into "neighborhood" subgroups, it is possible to examine variation in the proportion of victims reporting their victimizations to the police. For most victims it was possible to obtain "neighborhood characteristic" information. This information is derived by the Bureau of the Census through an aggregation process in which census tracts are combined to form larger units that are relatively homogeneous with respect to income, housing, and population characteristics. The Census Bureau's term, neighborhood characteristic, is a misnomer because it connotes aggregates of *contiguous* census tracts which is not necessarily the case. Our use of these data, however, will be limited to using the neighborhood characteristics to categorize areas into more homogeneous subgroups. It is primarily the similarity of areas, for example in wealth, rather than contiguity that appears to be most relevant to Black's theory of law.

Table 3 displays the percentages of survey victimizations reported to the police by seriousness level and the proportion of

⁵ In connection with the data reported in Table 2 it is important to note that there is some evidence from reverse record checks that victimizations between persons known to each other are somewhat less likely than victimizations between strangers to be mentioned to survey interviewers (Law Enforcement Assistance Administration, 1972: Table 5). The first hypothesis tested with the data in Table 2 is unaffected by this factor, because there is no evidence of a differential in this bias as a function of income level. The second hypothesis, contrasting strangers and nonstrangers, is probably affected because nonstranger victimizations are disproportionately undercounted by the survey. This bias probably works against Black's hypothesis.

Table 2. Proportion of Victimization Reported to the Police by Seriousness Level, Family Income, and Prior Relationship between the Victim and Offender, United States, 1974-1976

Seriousness Level		Family Income						Total	Gamma
		Under \$3,000	\$3,000-7,499	\$7,500-9,999	\$10,000-14,999	\$15,000-24,999	\$25,000 or Over

Table 3. Proportion of Victimization Reported to Police by Seriousness Level and Ratio of Number of Families in Respondent's Neighborhood with Annual Incomes under \$5,000 to Total Families in Neighborhood, United States, 1974-1976

Seriousness Level	Proportion of Families in Respondent's Neighborhood with incomes under \$5,000				Total	Gamma
	0-10%	11-20%	21-30%	31-100%		
1	35% (1,108,504)	37% (1,524,432)	38% (839,712)	37% (745,554)	37% (4,218,202)	.023
2	37% (1,671,796)	37% (2,297,852)	41% (1,364,830)	41% (1,185,060)	39% (6,519,538)	.047
3	54% (1,126,276)	54% (1,641,788)	56% (997,065)	47% (989,873)	53% (4,755,002)	-.051
4	75% (393,980)	75% (608,400)	73% (419,024)	70% (506,002)	73% (1,927,406)	-.069
Total	45% (4,300,556)	46% (6,072,472)	48% (3,620,631)	46% (3,426,488)		.026

families within the victim's neighborhood with annual family incomes of less than \$5,000. According to Black's theory of law, as the proportion of families under \$5,000 increases, the rate of reporting to the police decreases. Once again, even at this level of aggregation, reporting is consistently related to seriousness level within each category of neighborhood income level. There is, however, little systematic evidence to support the proposition derived from Black's theory of law. In addition, when the data are regrouped according to the percentage of all families with an annual family income of \$15,000 or more, the very slight effect in Table 3 changes to a trend of a similarly weak magnitude *opposite* to that predicted by his theory. In sum, areal stratification does not produce findings of notable magnitude nor findings consistently in the direction required by the theory.

Morphology

The second dimension relevant to Black's (1976:37) theory of law is morphology:

Morphology is the horizontal aspect of social life, the distribution of people in relation to one another, including their division of labor, networks of interaction, intimacy, and integration. It varies across social settings of every kind, whether societies, communities, neighborhoods, or organizations. . . . One village or tribe may have a greater division of labor—more differentiation—than another Some settings are intimate, others im-

personal. In some, nearly every one participates in everything) in others, many are marginal or alone.

Morphology is a central dimension in *The Behavior of Law* because of its implications for the degree to which people are involved in each other's lives (Black, 1976:40). Black contends that law is inactive among intimates and is used increasingly as relational distance increases, until the point at which people exist entirely independently of each other, a point rarely reached in modern societies. This observation is embodied in the proposition that "the relationship between law and relational distance is curvilinear" (Black, 1976:41). Up to a point, Black (1976:46) notes, a community's size is predictive of its rate of litigation.

This derivation can be tested with the victimization survey data by examining the relationship between the size of the community in which the victim resides and the proportion of respondents who told interviewers that they had reported the victimization to the police. From the victimization data it is possible to obtain the size of the place in which the respondent resided at the time of the interview. These place sizes have been divided into six groups as shown in Table 4. According to Black's theory of law, as place size increases, so too should the proportion of victimizations reported to the police.

The data in Table 4 do not support the hypothesis. At each seriousness level the general trend is for the rate of reporting to

Table 4. Proportions of Victimitizations Reported to the Police, by Seriousness Level, and Size of Place, United States, 1974-1976^a

Seriousness Level	Place Size						Total	Gamma
	Under 10,000	10,000-49,000	50,000-249,000	250,000-499,999	500,000-999,999	1,000,000 or more		
1	44% (546,280)	37% (957,077)	37% (970,599)	34% (309,680)	31% (457,445)	32% (466,765)	36% (3,707,846)	-.112
2	46% (792,968)	38% (1,385,821)	37% (1,395,100)	33% (540,047)	38% (730,028)	38% (776,311)	38% (5,620,275)	-.060
3	53% (629,018)	57% (1,001,677)	54% (980,465)	49% (405,247)	50% (505,470)	54% (646,540)	54% (4,168,417)	-.034
4	82% (201,721)	73% (361,688)	76% (345,854)	70% (170,045)	68% (238,581)	72% (406,385)	73% (1,724,274)	-.096
Total	51% (2,169,986)	46% (3,706,262)	45% (3,692,019)	42% (1,425,018)	43% (1,931,525)	47% (2,296,001)		-.041

^a Cases in which the place size has not been classified by the Bureau of the Census are not included in this table.

the police to decrease as the size of the place in which the respondent lives increases.

Among morphological variables Black includes radial location, the proximity of individuals to the center of social life. Employed persons are more integrated than unemployed and married persons are more integrated than single persons (Black, 1976:48). The proposition related to radial location is that "law varies directly with integration" (1976:48). From this it follows that (other things being equal), for example, persons who are unmarried and unemployed will have lower rates of reporting to the police than will persons who are married and employed. To test this proposition, respondents were categorized with respect to marital status and employment status. For this purpose, persons keeping house were categorized as employed.⁶

Table 5 shows rates of reporting to the police by employment status and marital status. A comparison of proportions reporting their victimizations to the police among those who were married vs. those who were never married indicates that the former are more likely than the latter to invoke the criminal justice process. This tendency is slightly greater for less serious victimizations.⁷ Because Black views

married people as more integrated than single people these results are consistent with his radical location hypothesis. Employment status, a second indicator of social integration, however, is not consistently related to reporting to the police in the direction predicted by Black's theory of law. Furthermore, to the extent that being in school is viewed as being more integrated than being unemployed, the data are generally inconsistent with the integration proposition.⁸ For example, among persons who have never been married, those in school were *less* likely than those unemployed to report victimizations to the police (e.g., seriousness level 1, 29% vs. 35%).

Black also hypothesizes that the quantity of law is related to population density. The greater the density, the greater the law. A density indicator available among the neighborhood characteristics is the ratio of the number of housing units in structures containing five or more units to the total number of housing units. Contrary to his theory of law, there is a slight trend for the proportion of victimizations reported to the police to decrease as population density increases (data not shown in tabular form). For the least serious victimi-

⁶ The "other" category shown in Table 5 includes retired persons and persons who were unable to work. When tabulated separately "persons keeping house" were found to have rates of reporting similar to those of employed persons.

⁷ Because of the number of cells in relation to the

number of unweighted cases available, for this portion of the analysis it was necessary to dichotomize seriousness. Low seriousness includes Sellin-Wolfgang scores 0 through 3 and high seriousness includes scores of 4 or more.

⁸ Respondents were dichotomized into those under 35 and those 35 and older and these findings maintained.

Table 5. Proportion of Victimization Reported to the Police, by Seriousness Level, Marital Status, and Employment Status, United States, 1974-1976

Seriousness Level	Marital Status											
	Married				Widowed, Separated or Divorced				Never Married			
	Employed	Un-employed	In School	Other	Employed	Un-employed	In School	Other	Employed	Un-employed	In School	Other
1	49% (3,488,813)	48% (99,039)	40% (69,024)	49% (158,301)	46% (1,455,632)	40% (77,181)	58% (41,057)	39% (207,950)	35% (2,003,256)	35% (234,409)	29% (1,186,356)	35% (83,550)
2	70% (2,282,872)	61% (106,637)	51% (60,926)	64% (159,788)	64% (1,046,157)	62% (83,265)	61% (38,268)	64% (157,244)	55% (1,337,286)	52% (191,035)	44% (670,096)	65% (56,733)

zations, 40% of victims residing in areas with no housing units in structures containing five or more units and 32% of victims residing in areas with more than 15% of housing units in structures containing five or more units, reported their victimizations to the police. For the most serious victimizations, the respective figures are 75% and 71%. Thus, among those morphological propositions tested, only that relating to greater reporting by married than single persons received support.

Culture

The third dimension discussed by Black (1976:61) is culture:

Culture is the symbolic aspect of social life, including expressions of what is true, good, and beautiful. It thus includes ideas about the nature of reality, whether theoretical or practical, and whether supernatural, metaphysical, or empirical. . . . Culture includes aesthetic life of all sorts, the fine arts and the popular, such as poetry and painting, clothing and other decorative art, architecture, and even the culinary arts.

Like stratification, culture varies among societies and within societies among individuals. "An individual's culture depends upon how many ideas he has, what he wears, eats, makes, watches, and plays" (Black, 1976:64). As an indicator of the culture of individuals, Black uses education. Whether on the individual or societal level, "law varies directly with culture" (Black, 1976:63). That is, for example, "literate and educated people are more likely to bring lawsuits against others" (Black, 1976:64).

The left panel of Table 6 shows again that the seriousness of the victimization is closely related to reporting to the police. Regardless of an individual's educational level, more serious victimizations are more likely to be reported to the police. The victim's educational level (excluding those still in school), as Black's theory predicts, is directly related to reporting to the police. The overall strength of this relationship is, however, very weak. Collapsing across seriousness, the gamma for the relationship between individual educational level and reporting to the police is .109 and within seriousness rows gammas

Survey includes a survey of a national probability sample of business establishments it is possible to compare reporting rates according to whether the victim was an individual or an organization. In support of Black's hypothesis, the data indicate that although about one-half of the robberies of individuals are reported to the police, more than four out of five robberies of business establishments are reported to the police.

Black also conceives of organization as applying to individuals and to collections of individuals. Black considers two or more individuals, by definition, to be more organized than a single individual. As noted above, Black puts forth the proposition that "law is greater in a direction toward less organization" (Black, 1976:86). If victims of personal crimes are dichotomized into less organized (single individuals) and more organized (two or more individuals) and offenders are similarly dichotomized, Black makes an explicit prediction regarding the rank-order of the resultant four-fold classification with respect to invocation of law. Specifically, the most likely to report their victimizations to the police are two or more persons who are victimized by a lone individual, then two or more persons victimized by two or more offenders, then a lone victim of a lone offender, and finally the lone victim of two or more offenders (Black, 1976:97). The relevant data are presented in Table 7. With seriousness level controlled, the rank-order of cells does not consistently conform to predictions derived from Black's theory of law. This is because although there is a systematic "victim" effect along the organizational dimension, there is not a

parallel systematic "offender" effect along this dimension. In sum, there is evidence consistent with the theory that more organized victims are systematically more likely to invoke the law, but there is no consistent (or substantial) evidence that "the more organized the offender, the more of this immunity [from law] he enjoys" (Black, 1976:93). Once again, a comparatively strong seriousness effect is apparent.

Social Control

Black's (1976:107) final dimension is social control:

Social control is the normative aspect of social life. It defines and responds to deviant behavior, specifying what ought to be: what is right or wrong, what is a violation, obligation, abnormality, or disruption. Law is social control, but so are etiquette, custom, ethics, bureaucracy, and the treatment of mental illness.

As with the other dimensions relevant to the behavior of law, social control is a quantity that varies across societies, communities, organizations, families and friendships—a quantity with which law varies inversely (Black, 1976:107). In settings which permit people continuously to observe and react to each other's conduct, law is less important as a mechanism of social control. This proposition can be tested by examining variations in reporting victimizations to the police across rural, suburban, and urban areas. Much of Black's discussion implies that in rural areas, in which informal controls are traditionally viewed as stronger than in anonymous cities, rates of reporting to the police will be lower than those in urban

Table 7. Proportion of Victimizations Reported to the Police by Seriousness Level, Number of Victims, and Number of Offenders, United States, 1974–1976

Number of Offenders	Seriousness Level							
	1		2		3		4	
	Number of Victims One	Number of Victims More Than One	Number of Victims One	Number of Victims More Than One	Number of Victims One	Number of Victims More Than One	Number of Victims One	Number of Victims More Than One
One	34% (2,618,328)	55% (450,508)	36% (3,564,729)	53% (738,883)	44% (2,390,365)	66% (940,594)	71% (791,691)	86% (159,048)
More Than One	34% (989,576)	59% (360,232)	38% (1,556,805)	54% (593,099)	49% (1,003,481)	69% (672,093)	70% (693,466)	80% (294,856)

areas. When the victimization data are disaggregated according to the place of the victim's residence (data not shown in tabular form)—within the central city of an SMSA (urban), the balance of an SMSA (suburban), or outside an SMSA (rural)—there is virtually no relationship between urbanization and reporting to the police. For the least serious victimizations, the percentages of victims reporting to the police in urban, suburban, and rural areas are 36%, 40% and 40%. For the most serious victimizations the respective figures are 74%, 82% and 79%.

Social control is hypothesized not only to vary across macroareas but across microareas as well. Black (1976:110) maintains that private social settings have more social control (other than law) and, as a consequence, less law than do public settings. In connection with reporting crimes to the police, it follows from this premise that reporting should be greater for victimizations occurring in public

places ("on the street" and in public conveyances) than in homes or offices. The relevant data are presented in Table 8.

The most private of the places shown in Table 8 is the home and the least private is "on the street." These data are contrary to the prediction that where nonlegal social control is the greatest (the home), reporting to the police will be the least and, conversely, where nonlegal social control is the least (the street), reporting to the police will be the greatest. For each seriousness level rates of reporting to the police for victimizations occurring on the street were lower than those for victimizations occurring in the home. They were also lower than the rates for victimizations occurring "near the home," where social control would be expected to be greater because the crime occurred within the victim's own neighborhood (Black, 1976:109). As a place of occurrence, "office/factory" is, in Black's terms, subject to more nonlegal social control than

Table 8. Proportion of Victimization Reported to the Police, by Seriousness Level, Place of Occurrence, and Prior Relationship between Victim and Offender, United States, 1974-1976

Seriousness Level	Place of Occurrence							Total
	Own Home	Inside Commercial Building/Public Conveyance	Office/Factory	Near Home	On Street	Inside School	Other	
stranger	64% (109,687)	40% (563,677)	54% (20,931)	41% (203,340)	38% (1,579,663)	14% (292,063)	46% (241,930)	38% (3,011,291)

the street. Rates of reporting are higher (but not consistently) for crimes occurring on the street than for those occurring in offices and factories. Victimizations taking place "inside schools" have the lowest rates of reporting to the police, regardless of seriousness level. To the extent that the school is viewed as an institution having its own independent system of social controls, then these school data are supportive of Black's proposition.

Also shown in Table 8 are rates of reporting to the police disaggregated on the basis of prior relationship between the victim and the offender. This is useful for two reasons: first, because as place of occurrence varies so too does the proportion of incidents involving victims and offenders who were previously known to each other (e.g., victimizations occurring in the victim's home involve a disproportionate number of nonstranger victimizations); second, because Black suggests that increased social control in private settings derives both from the fact that persons interacting in private settings are likely to be friends and acquaintances (among whom on-going nonlegal mechanisms of social control exist) and that many restricted places (factories, offices, schools, etc.) have their own systems of security (Black, 1976:110). When the prior relationship between the victim and the offender is controlled, the overall findings noted above generally maintain. One exception is that stranger victimizations occurring in offices/factories have rates of reporting that are generally higher than those occurring between strangers on the street.

Black argues that law varies even with the time of day. "When people go to sleep, for instance, most social control relaxes as well and law increases" (1976:110). Consistent with this hypothesis is the finding that for victimizations of low seriousness reporting to the police increases from one-third for those victimizations occurring during the daytime to one-half for those occurring between midnight and six a.m. As seriousness increases, the strength of this relationship decreases, such that for the most serious victimizations there is little variation in reporting to the police by time of occur-

rence (daytime, 74%; 6 p.m. to midnight, 75%; midnight to six a.m., 72%). Thus, overall, the social control dimension receives only partial support.

Discussion

The Behavior of Law is an important contribution to the sociology of law both because of the empirical questions that it raises and because it is generally set forth in such an explicit manner that it is testable. Black predicts that law, which can be quantified in a variety of ways, is associated with several critical dimensions; Black predicts the direction of these associations, and the conditions under which these associations hold. Through the use of a great variety of concrete examples Black facilitates the research task by translating central concepts into indicators.

The ability of Black's theory to explain reporting to the police can be summarized briefly. According to the stratification postulates of Black's theory of law as they have been operationalized here, reporting to the police should have varied directly with the victim's rank, should have been greater for victimizations among wealthy nonstrangers than among less wealthy nonstrangers, should have been greater for victimizations between strangers than for victimizations between nonstrangers, and should have varied directly with areal income. With the exception of a slightly greater overall rate of reporting for stranger victimizations than for nonstranger victimizations, these stratification propositions were not supported.

The propositions relating to morphology lead to the expectation that law will be used increasingly as relational distance increases. In the context of reporting victimizations to the police, this implies that reporting will be greater for larger communities than for smaller communities and for more densely populated areas than for less densely populated areas. The proposition that law varies directly with integration implies that reporting to the police will be greater for employed persons than for unemployed persons and for married persons than for single persons. Of these four morphological expectations support

is found only for the hypothesis that married persons have a higher rate of reporting to the police than do single persons.

Following Black, educational level was used as the indicator of individual and neighborhood culture to test the proposition that law varies directly with culture. Although there is weak support for this proposition on the individual level, there is weak evidence contrary to the hypothesis on the areal level. At neither the individual level nor the areal level is the relationship between education and reporting to the police as substantial as required by Black's theory.

Black proposes that law varies directly with organization and hence the finding that business establishments have a higher rate of reporting to the police than do individuals is consistent with Black's organizational hypothesis. On the other hand, his theoretical predictions regarding variations in rates of reporting to the police according to whether the victim and the offender have greater or lesser organization are not consistently supported. The organization of the victim is associated with greater reporting to the police but, contrary to theoretical expectations, the organization of offenders does not reduce reporting to the police.

The proposition that law varies inversely with other forms of social control was operationalized by examining rates of reporting by extent of urbanization, time of occurrence, and place of occurrence. Rates of reporting were found to be homogeneous across levels of urbanization, but were found to vary somewhat across time and place of occurrence. Although the data relating to time of occurrence for victimizations of low seriousness are consistent with Black's theoretical predictions, those relating to extent of urbanization are not, and those relating to place of occurrence offer only partial support.

Most of the predictions of Black's theory of law are not compatible with these victimization survey data on the invocation of the criminal law. For a theory that purports that "... it is possible to explain all of [the behavior of law]" (Black, 1976:4), these results cannot be considered encouraging. On the other

hand, at the trivariate level, when the dimensions central to Black's theory of law are controlled, in every case there is evidence of a substantial seriousness effect. This is true when both characteristics of individuals (Tables 1, 2, 5, and 6) and characteristics of areas (Tables 3, 4, and 6) are controlled. Also, without exception, at the trivariate level the seriousness effect is greater—usually much greater—than the effects of the indicators central to Black's theory of law. In the few instances in which there is some support for Black's hypotheses, the strength of support decreases as seriousness increases.

The centrality of seriousness to the phenomenon of reporting to the police, particularly in conjunction with the relative weakness of the dimensions at the core of Black's theory of law, suggests that an adequate theory of criminal law must incorporate some measure of the consequences of legal infractions to individuals in order to be an accurate model. It is, of course, conceivable that the relation between variability in conduct and variability in the behavior of law is confined to reporting of victimizations to the police and is not of importance to the quantity of criminal law in other spheres. However, research concerning arrest (Hindelang, 1974; Hagan, 1972; Goldman, 1963), prosecution (Hagan, 1974) and sentencing (Green, 1964; Hagan, 1974; Chiricos and Waldo, 1975) indicates that the gravity of the infraction against legal norms is a major determinant of the quantity of criminal law in general.

To be consistent with the available data, an adequate theory of the behavior of criminal law must incorporate a proposition stating that the quantity of criminal law varies directly with the seriousness of the infraction. That is, the gravity of the infraction against legal norms is a major determinant of how individuals and legal systems react to the infraction. Such a proposition, however, is explicitly ruled out of Black's theory by his stance that the behavior of law can be explained "... without regard to the ... conduct of the deviant" (Black, 1976:118). By excluding individual conduct from his theory, Black has excluded what our data

(and the data of others cited above) have shown to be an extremely important determinant of the quantity of criminal law.

Unlike Black's definition of seriousness (cited above), seriousness as we have conceptualized and operationalized it can be defined independently of the quantity of law. The available research data support the notion that within societies there is general consensus regarding the rank order of common-law infractions by seriousness (Rossi et al., 1974). Specifically, it has been found that such rankings are generally consistent (i.e., correlations on the order of .9) across social class, education, race, sex, and age (Rossi et al., 1974). Furthermore, replications of the Sellin-Wolfgang seriousness scale in Canada (Akman et al., 1967), in Puerto Rico (Velez-Diaz and Magargee, 1971), and in England, Taiwan, Brazil, and Mexico (Pease et al., 1975) show a general cross-cultural consensus as well. These studies suggest that within and across societies there is general agreement on elements of many criminal infractions that make them more or less serious.⁹ The data indicate that variation in these elements of seriousness substantially affects variation in the quantity of law and cannot be ignored if the theory is to model the behavior of the criminal law.¹⁰

¹⁰ Although it seems as though seriousness also would be predictive of invocation of the law in some other spheres as well (e.g., civil), we have limited our discussion of the behavior of law to the *criminal* law. Thus, Black's theory is much more general (in applying to all of law) and we do not maintain that our seriousness model would work as well—or Black's theory as poorly—if tested in contexts outside of the criminal law.

COMMON SENSE IN THE SOCIOLOGY OF LAW*

DONALD BLACK

*Yale University**American Sociological Review* 1979, Vol. 44 (February):18-27

The effort by Gottfredson and Hindelang (1979) to test some of the theory in *The Behavior of Law* (Black, 1976) is worthy of comment, since it illustrates how sociologists can be misled by common sense. First, because they employ data from surveys of "criminal victimization," conduct not considered "crime" by the respondents was lost from view, making a test of the theory impossible. Second, because they attempt to explain law with the "seriousness" of crime, they mistake an evaluation for a description, thereby offering as a solution what is in fact a problem in the sociology of law. The weaknesses in Gottfredson and Hindelang's work may be found in the study of law more generally, and also in the study of other phenomena in sociology.

Common sense is the style of discourse by which people understand reality in everyday life. It is a guide to practical action, and is radically different from science in its pure form (see Schutz, 1953; Garfinkel, 1960; Geertz, 1975). One difference is that, unlike science, common sense does not distinguish sharply between facts and values.¹ Instead, evaluations of reality appear in a rhetoric of description, so that statements about what is or is not desirable are presented as if they were statements about what is simply the

case. A seemingly descriptive word such as "art," for example, actually means in common sense that something is worthy of aesthetic appreciation, just as "illness" refers to something that is worthy of medical attention. Similarly, the taste of one kind of food or drink is said to be "better" than another kind, as if this were a matter of fact, something about the food or drink rather than about the person who consumes it. Whatever the topic may be—the weather, a suit of clothes, or a person—an evaluation in common sense tends to sound like a description.

Partly because of this, common sense may enter unnoticed into the discourse of science. The "facts" may then contain hidden meanings, and scientists may unwittingly report as findings or even promote as theory what is actually common sense itself. Since it is a study of human behavior, sociology may be especially vulnerable to problems of this kind. In any case, if only because it is a science, sociology in its pure form involves an understanding of reality which is different from that of common sense. Consider the sociology of law.

In common sense, law is, among other things, a way of achieving order and jus-

I thank M.P. Baumgartner for criticizing an earlier draft.

¹ Other characteristics of common sense are discussed by Geertz (1975). For example, practitioners of common sense are less skeptical than scientists. The nature of reality is taken for granted: it is "of course" the case, what "everyone knows," what is "obvious" to anyone with "ordinary intelligence." Unlike science, then, common sense requires no expertise. Without special preparation or effort, anyone can and should have a good deal of common sense. For that matter, people in everyday life do not even recognize common sense to be a body of ideas, but take it to be a product directly derived from experience, an expression of reality itself.

tice. It proceeds through the interpretation and application of rules, case by case, within the legal process, and its primary concern is conduct. Thus, in the common sense of criminal law, the conduct known as "crime" explains why people call the police, and it also explains arrest, prosecution, conviction, and punishment. It is understood, furthermore, that the more "serious" the crime is, the more likely is each of these actions. By contrast, the sociology of law in its pure form understands law as a quantitative variable, and every increase of governmental social control—by a call to the police, an arrest, a conviction, etc.—is taken as an increase in this quantity (see Black, 1976:2–3). A major aim is then to predict and explain variation in the quantity of law with its location and direction in social space, defined by the characteristics of the people involved, their relationships with each other, and the larger social context in which they interact.² It should be noted that from this standpoint the nature of "crime" and its "seriousness" are expressions of law itself, since law defines the conduct to be known as "crime" and the degree to which it is to be handled as "serious." In this respect as well as others, the sociology of law departs considerably from the common sense of law, that is, from the discourse of lawyers, judges, policemen, citizens, or anyone else who relates to law as a practical affair. It is therefore worthy of comment that two sociologists, Michael R. Gottfredson and Michael J. Hindelang, have written a paper arguing that "crime" itself explains why people call the police, and that, in particular, the "seriousness" of crime is the most important factor in the likelihood of these calls (1979). The publication of the paper in a leading journal indicates that common sense is not yet fully recognized as such in the sociology

of law or, for that matter, in sociology at large. Because it has this broader significance, then, a closer examination of the paper is warranted.

A STUDY IN COMMON SENSE

Using interviews collected in several surveys of "criminal victimization" in the United States, Gottfredson and Hindelang have sought to discover differences across the population in the likelihood of calls to the police. More specifically, they have sought to determine whether there are differences in calls to the police as predicted by some of the theory in *The Behavior of Law* (Black, 1976, hereafter, "the theory of law"). The theory predicts, for example, that—all else constant—a wealthier person is more likely to call the police than a poor one, an employed or married person more likely than an unemployed or single one, an organization more likely than an individual, or the victim of a stranger more likely than the victim of an intimate. Gottfredson and Hindelang report, however, that differences of this kind generally do not predict who calls the police. Instead, they find that the "seriousness" of the "crime" is what makes the difference: "... the seriousness effect is greater—usually much greater—than the effects of indicators central to Black's theory of law" (p. 16). Leaving aside matters of a strictly technical nature—such as how they measure variables and their effects—the following discussion focuses upon two problems at a deeper and more fundamental level of Gottfredson and Hindelang's study. First, because the incidents labelled as "crimes" for purposes of their study were selected by the respondents, variation in the labelling process itself was completely obscured, making it impossible to test the theory of law with their data. Second, when they attempt to explain calls to the police with the "seriousness" of crime, they mistake a variable that requires explanation for one that provides it. In the first case Gottfredson and Hindelang fall prey to the common sense of the respondents, in the second to their own common sense.

² It should be added that variation in the quantity of law is only one among a number of problems addressed by the sociology of law. For instance, there is also variation in the form and style in which law presents itself. The quantity of law is the focus of the present discussion, however, since it bears most directly upon the issues treated in the following pages.

The Nature of Crime

A risk of any study involving interviews is that the meaning of the questions or answers may not be clear, and the findings produced may therefore not be what they seem. For this reason, the questions should be as concrete as possible, requiring a minimum of interpretation, and they should be designed to elicit equally concrete answers. Thus, in a survey about criminal or other legal matters, the questions and answers should pertain to simple matters of fact, since the meaning of legal terminology is by its nature ambiguous and applicable to a variety of facts. The concept of "crime" itself is inherently vague, for example, and different people may apply it in different ways. What is a "crime" to one person may not be to another, and, for a given person, whether an incident is a "crime" may depend upon the conditions under which it occurs. This is because, in common sense, what is a "crime" is not merely a matter of fact; it is also an evaluation. It is a code word that implies how an incident should be handled along with, to some degree, what the incident is. In particular, in the discourse of everyday life, a "crime" is an incident worthy of police attention.³ Hence, the concept of "crime" does not describe the universe of incidents people experience in their everyday lives, but only the ones they consider worthy of police attention. The same applies to related terms of art in legal discourse, such as "theft," "robbery," "assault," or "rape."⁴

³ The phrase "worthy of police attention" is used here for the sake of simplicity, but it should be understood that, in common sense, a "crime" is worthy of other legal attention as well, such as prosecution and adjudication. It is, moreover, an incident worthy of legal attention in the penal style, which involves, among other things, the definition of a person as an offender who has violated a prohibition and who deserves punishment in the name of the state. This contrasts with other styles of social control such as compensation and therapy (see Black, 1976:4-6). Finally, it should be realized that simply because a person considers an incident worthy of police attention does not mean the police will actually be called.

⁴ The same applies to legal discourse in general, civil as well as criminal, and procedural as well as substantive. When lawyers, judges, or law professors talk or write about legal matters, they generally make them sound as if they were all matters of fact. Some know what the law "is," they suggest, while

The survey data analyzed by Gottfredson and Hindelang were spoiled for their purposes by this confusion about the nature of "crime." Because the respondents were asked only to report incidents they considered to be "crimes," incidents not labelled as such were never mentioned or collected in the interviews. As a result, the data can tell us only about the incidents considered worthy of police attention and nothing about the others, making a comparison impossible. This means that the predictions about calls to the police implied in the theory of law cannot be tested with these data.⁵ Perhaps a few examples from the interview itself will show how the data were spoiled.⁶ On the first page of the interview schedule, at the top, is the title of the project: "National Crime Survey." Since this title presumably was given when each interview was arranged, from the beginning anyone in touch with everyday language could understand the aim of the study: to survey incidents worthy of police attention. Beyond this, the core of the interview began with the following introduction: "Now I'd like to ask some questions about crime." Next came a series of screen questions pertaining to whether the respondent had been the victim of various kinds of "crime." These questions ask, for instance, whether the respondent had been the victim of a "stickup" or "mugging," and the concepts "rob" and "steal" appear as well. After these specific questions, the respondent was asked whether anything else had happened that he or she "thought was a crime." Finally, for each "crime" mentioned, a detailed "crime incident report" was filled out,

others do not. They discuss what "is" constitutional, for example, or what "is" negligence, fraud, a contract, a search, or whatever. And yet all of this is greatly concerned with matters of value, of what ought to be the case, of who ought to be allowed to do this or that.

⁵ This is not to say that the data are inappropriate for the purpose for which they were gathered in the first place—government surveys of "criminal victimization," in other words, the "crime problem." In fact, "crime" in its everyday meaning would seem to be exactly what such surveys are intended to examine.

⁶ A copy of the interview schedule is reproduced in Garofalo and Hindelang (1977: Appendix A).

and it also implied that the matter at hand was police business. Surely we may infer that the respondents did not report incidents they considered to be, as a practical matter, different from "crimes."

What people consider to be "crime" varies with its location and direction in social space. Any given person will describe some conduct as "crime"—or "robbery," "theft," "rape," etc.—but this will depend upon such factors as the social status of the people involved as "offender" and "victim," the nature of the relationship between them, and the larger context in which the incident occurs. Thus, what is an "assault" or "theft" in one setting is only "teaching someone a lesson" or "borrowing without asking permission" in another setting. Acts committed by higher-status people against those of lower status, for example, or by organizations against individuals, or between intimates, are less likely to be defined as "crimes." Accordingly, a parent who strikes or beats a son or daughter has not committed what is generally defined as an "assault," nor has a man who strikes or beats his wife or girlfriend. Likewise, a man who forces sexual relations upon his wife or girlfriend is generally not considered a "rapist," and if he absconds with her welfare check or automobile he is not a "thief." All of this is common sense (see Sudnow, 1965).

The theory of law predicts and explains common sense of this kind, showing how the label of "crime"—or "assault" or "rape" or "theft"—is distributed in social space. But it is precisely this variation in labelling that is obscured in the data employed by Gottfredson and Hindelang. Their study therefore shows only what the labels predict, not what predicts the labels. It shows only whether people called the police when they considered an incident worthy of police attention, not whether some incidents were more or less likely to be considered worthy of this attention in the first place.

Gottfredson and Hindelang indicate in a footnote that they had some awareness of this problem, since they cite evidence that "... nonstranger victimizations are disproportionately undercounted by the survey" and that "this bias probably works

against Black's hypothesis [about the effect of intimacy on the labelling of crime]" (fn. 5). Nevertheless, they apparently did not recognize the broader implications of this for the validity of their study.⁷ It should be noted, moreover, that this "bias" in Gottfredson and Hindelang's data is predictable from the theory they attempted to test with the data (Black, 1976:41, 47). The theory of law also predicts a number of other "biases" in their data, such as a tendency to omit incidents with lower-status victims, including poor people, blacks, juveniles, and individuals (rather than organizations). Wherever the theory of law predicts the quantity of law to be the least, in fact, it also predicts that the "victimization survey" will collect the

⁷ The evidence that "crimes" between intimates were "underreported" is that people who had actually called the police about such matters often failed to report to interviewers that the incidents had ever occurred at all. This was learned through "reverse record checks," whereby incidents found in police records were traced back to the people involved in order to determine whether they would be reported to an interviewer. In studies of this kind, it was found that only about 70% of the victims known to the police reported their "victimizations" to the interviewers. This varied with the nature of the incident, so that, for example, 90% of the known "burglaries" were reported, but fewer than half of the known "assaults" (for an overview of these studies, see Garofalo and Hindelang, 1977:12-4).

These findings may reflect the fact that people sometimes call the police even though they do not consider the matter a "crime." In cases of violence between a husband and wife, for instance, often the victim simply wants the police to settle a dispute or wants nothing more than to be taken to a hospital (see, e.g., Parnas, 1967). When asked by an interviewer about "crimes" they have experienced, then, such people would not report these cases. Underreporting of this kind should be even greater for cases that were never reported to the police in the first place.

Regardless of the vocabulary used, however, it is unlikely that any survey based upon interviews would be able to elicit an unbiased picture of the past, especially in matters of human conflict. In a study of conflict in another society, for example, it was found that in interviews people were less likely to remember and report incidents that were handled privately, and also those that were not handled at all. This was discovered by comparing the reported cases—called "memory cases" by the investigator—with those which the investigator directly observed while living among the people (Koch, 1974: 23-4). Data based upon direct and unobtrusive observation would therefore appear to be the most reliable way to test the theory of law or any other theory of social control.

fewest cases. And this is entirely independent of the conduct that actually occurred.

This error in Gottfredson and Hindelang's study—allowing the common sense of the respondents to define "crime"—is essentially the same as the well-known error of using official statistics about "crime" to measure actual conduct, since these data are products of common sense as well. We know, for example, that the police are less likely to record an incident as a "crime" if it occurs between people in an intimate relationship (Black, 1970:740-1). In the view of the police, a typical case of violence between a husband and wife is "not really a crime" but only a "family dispute" (see Parnas, 1967), and what might otherwise be called a "theft" is only a "civil matter" when it occurs between people related by blood or marriage. There is also evidence that the police are less likely to record as a "crime" an incident involving people of low status (see, e.g., Black, 1970:745-6). Similar processes of selection—according to the same principles—occur at other stages of the criminal process, such as in the charging and prosecuting of offenses against persons accused of crimes, and, in fact, wherever else cases of any kind are labelled according to legal criteria. If we are to learn how these labels are applied, then, we must examine all of the cases involving the same conduct, regardless of how they have been classified by people in everyday life. Although sociologists have long been skeptical of crime statistics provided by the police, they do not appear to be sufficiently skeptical of crime and other statistics provided by ordinary citizens.

The Seriousness of Crime

Gottfredson and Hindelang report little evidence supporting the theory of law, but they do find one major correlation: calls to the police vary directly with the "seriousness" of crime. They argue that the relevance of this finding extends beyond calls to the police to every stage of the criminal process, and accordingly they offer the following proposition: "The quantity of criminal law varies directly with the seriousness of infractions" (p. 6). In this part

of their work Gottfredson and Hindelang have not merely recorded the common sense of their respondents; here they have promoted common sense as sociological theory.

To explain the response to crime with its "seriousness" is much the same as explaining the response to art with its "beauty" or the response to an idea with its "truth." It is to confuse the participant's perspective with the observer's perspective, and even to confuse the thing to be explained with that which explains it. The "seriousness" of crime is an evaluation, not a fact, and so it cannot be measured without a standard of value. Like the concept of crime itself, it is a justification for law, not an explanation. Despite all of this, the effort to explain variation in law with the "seriousness" of crime continues as an established practice in the sociology of law.⁸ Gottfredson and Hindelang's work thus provides an opportunity to examine an error that is common to the field. Their work also provides an example of the error in a particularly sophisticated form.

Gottfredson and Hindelang do not themselves judge the "seriousness" of crime, nor do they invoke the hierarchy of crimes specified in the written law or implied in the law in action. Instead they employ what they call a "seriousness scale." This scale was developed earlier by Thorsten Sellin and Marvin E. Wolfgang (1964: especially chap. 15 and 16), and was originally intended to define the degree of "harm" entailed in various kinds of conduct, such as the violent and predatory conduct often labelled as "assault," "rape," "robbery," etc. The scale allows comparisons of the "seriousness"

⁸ For instance, the "seriousness" of the crime is commonly understood as a factor in the severity of sentences in criminal courts. In fact, this is taken for granted in the design of many studies. Thus, in one recent investigation, "seriousness of offense" is called a "significant variable" and is therefore held constant while other variables are examined (Chiricos and Waldo, 1975:759; for a review of studies that follow a similar strategy, see Hagan, 1974). The "seriousness" of conduct is also seen as important in juvenile dispositions (e.g., Terry, 1967; Cohen and Kluegel, 1978). Among other places, this idea can even be found in the present author's earlier studies of the police (e.g., Black, 1970; 1971).

of crime from one offender to another, or from one community or neighborhood to another, without reference to the actual response of legal agencies. Sellin and Wolfgang based their scale upon the attitudes of respondents who answered a "seriousness questionnaire." The questionnaire contained a number of hypothetical incidents, and was introduced as follows: "This booklet describes a series of violations of the law; each violation is different. Your task is to show how serious you think each violation is . . ." (Sellin and Wolfgang, 1964:254, italics omitted). For respondents, they selected police officers, juvenile bureau officers, juvenile court judges, and university students—people that Sellin and Wolfgang felt would be especially likely to subscribe to the "middle-class value system" (1964:249). This was viewed as the appropriate basis for their seriousness scale, since "... the definition of crime and the administration of criminal justice are institutionalized expressions of the normative structure of the dominant middle class in American society" (1964:250). From the beginning, then, Sellin and Wolfgang were perfectly aware of the subjective character of judgments about the "seriousness" of crime. They simply wanted to measure objectively the judgments themselves, and to rank the "seriousness" of each kind of conduct accordingly (see Sellin and Wolfgang, 1964:237).

It should be noted, however, that the questionnaire on which Sellin and Wolfgang based their seriousness scale does not rank the "seriousness" of conduct alone, but of conduct occurring under particular social conditions. Although this may have been unintentional, it is understandable, since the respondents could not have judged each hypothetical incident without visualizing who was involved as the offender and the victim in each case. Hence, these conditions were supplied in the questionnaire itself. For instance, the hypothetical incidents generally suggested that the offender was a stranger to the victim. Thus, one incident was presented as follows: "The offender drags a woman into an alley, tears her clothes, but flees before she is physically harmed or sexually attacked" (Sellin

and Wolfgang, 1964: Appendix D). Here the respondent could easily surmise that this was meant to describe a woman's encounter with a stranger, not, let us say, her husband or boyfriend. The same applies to a description such as this: "The offender robs a victim of \$1,000 at gunpoint." For that matter, even the use of concepts such as "rape," "rob," and "steal" in the descriptions indicated to the respondents that the conduct occurred under conditions typically associated with these labels. These conditions necessarily entered into the seriousness scale itself, since it was based upon the results of the seriousness questionnaire. The degree of "seriousness" assigned to "forcible sex intercourse," for instance, was based upon the respondents' evaluations of that event when visualized between strangers, and the same applies to the other elements of crimes to which scores are assigned in the seriousness scale (whether the victim was injured, whether a weapon was used, etc.). Social conditions are always involved in any evaluation of "seriousness," and they will enter implicitly and unconsciously if they are not made explicit from the beginning. Thus, for example, a violent act within a family or between friends will not be evaluated in the same way as a violent act between strangers. It will generally be seen as less "serious." Even intentional homicide loses some of its "seriousness" when it occurs under the right conditions (see Rossi et al., 1974:228–9). For that matter, during a war or revolution, homicide loses its criminality altogether and becomes praiseworthy. In short, nothing is "serious" under all conditions.¹⁰

⁹ This is not merely speculation. A number of years after Sellin and Wolfgang's work, Rossi et al. (1974) administered a "seriousness" survey that systematically varied the offender-victim relationship in some of the hypothetical incidents, and they found that the "seriousness" rankings by the respondents varied accordingly. For example, "forcible rape of a stranger in a park" was ranked 13th among 140 hypothetical incidents, whereas "forcible rape of a former spouse" was ranked only 62nd. Similarly, "beating up a stranger" was ranked 64th, whereas "beating up an acquaintance" was ranked only 112th (Rossi et al., 1974:228–9).

¹⁰ Besides homicide, another kind of conduct often thought to be criminal—or at least highly

None of this is to deny that under the conditions implied in their questionnaire, Sellin and Wolfgang's seriousness scale is entirely objective. It objectively portrays the subjectivity of their respondents. Moreover, although it is based upon evaluations of conduct under particular conditions, the seriousness scale assigns "seriousness scores" only to elements of the incidents themselves, and so it is possible to apply the scale to any concrete case, regardless of the characteristics of the people involved.¹¹ The use of a weapon or an injury to the victim increases the seriousness score of any incident, for example, regardless of whether the offender is a stranger to the victim, a

member of the victim's family, a friend, or whatever. Gottfredson and Hindelang were therefore able to apply the scale to all of the incidents in their sample.

The seriousness scale tells us what people in everyday life consider to be more or less worthy of police attention. Just as "crime" is, in effect, a codeword for an incident that is worthy of police attention, so is each kind of crime, such as "rape," "robbery," or "theft." And some crimes are evaluated as more worthy of this attention than others: they are more "serious." Since this is what "seriousness" means, it is not surprising that, as Gottfredson and Hindelang found, incidents ranked higher on the seriousness scale are more likely to result in calls to the police.¹²

It appears, however, that Gottfredson and Hindelang have mistaken the objective character of the seriousness scale for the objective character of "seriousness" itself, as if "seriousness" were a fact about crime rather than a judgment about it. In other words, they seem to have mistaken an evaluation for a description of conduct. They even criticize the theory of law because it does not contain any statements about the "objective seriousness" of crime: "One of the major difficulties facing those who would test Black's theory of law is that he is not explicit about how the objective seriousness of the offense should be handled" (p. 4). They do not seem to realize that no questionnaire,

deviant—under all conditions and in all societies, is "incest." However, this label applies only to sexual conduct under particular social conditions, such as between a father and daughter or a mother and son, whereas under other conditions it is not subject to punishment of any kind. The particular sexual relationships that are defined as "incestuous" also vary from society to society.

Social conditions explain not only what is a "crime" or what is "deviant" in some other sense, but also what is "law" or other "social control." Thus, homicide is a "crime" under some conditions and "punishment" under others. (It may also be neither.) The same applies to beatings and other kinds of violence, the seizure of property, intrusions, humiliations, and so on. Whether conduct is "deviant" or whether it is "social control" should never be taken for granted, but should always be viewed as a problem for investigation.

¹¹ The scale is presented in Sellin and Wolfgang (1964:298) as follows:

ELEMENT	SCORE VALUE
Minor injury to victim	1
Victim treated and discharged	4
Victim hospitalized	7
Victim killed	26
Victim of forcible sex intercourse	10
Intimidated by weapon, add	2
Intimidation of persons in connection with theft, etc. (other than in connection with forcible sex acts):	
Physical or verbal only	2
By weapon	4
Forcible entry of premises	1
Value of property stolen and/or damaged:	
Under 10 dollars	1
10-250	2
251-2,000	3
2,001-9,000	4
9,001-30,000	5
30,001-80,000	6
Over 80,000	7
Theft of motor vehicle (recovered, undamaged)	2

¹² Gottfredson and Hindelang's study thus indicates that the elements in the seriousness scale are relevant to the range of incidents in their sample, i.e., incidents considered "crimes" by people in everyday life. It should be remembered, however, that an unknown number of incidents containing elements in the scale are not considered "crimes" by the people involved. This applies, for instance, to a great deal of violence in the family (see, e.g., Gelles, 1972: chap. 2). Indeed, many wives who are beaten or otherwise injured by their husbands believe that they deserve it (see, e.g., Parnas, 1967:952; Gelles, 1972:58-60). The present author's own research in progress also indicates that violence—even when it involves a weapon or physical injury—is not an important factor in the way the police handle conflicts between people in on-going relationships. Be all of this as it may, it is surely the case that, under given conditions, conduct such as violence is relevant to the behavior of law. The question is how this is to be understood in a theoretical framework (see below, p. 25, especially footnote 14).

scale, or other method can ever specify empirically what is or is not a "serious" crime. No matter how much people may agree about it,¹³ the "seriousness" of crime is a question of value, not fact, a response to crime, not a characteristic of crime itself. Accordingly, Gottfredson and Hindelang's effort to explain the response to crime with its "seriousness" reduces to an explanation of one response to crime by reference to another. But they make no effort at all to explain why people respond to anything as more or less "serious" in the first place, that is, to explain "seriousness" itself. In this sense, they appear to have mistaken the problem for the solution.

The theory of law specifies some of the conditions under which people respond to conduct as more or less "serious." Nevertheless, more work is needed on the problem of conduct itself. Even if the "seriousness" of conduct depends upon the social conditions under which it occurs, the fact remains that, under given conditions, some conduct is handled as more "serious" than other conduct. In a family, for instance, some acts of violence are handled as more "serious" than others, even if these evaluations are reversed under other conditions, such as during a war. Simply to designate conduct of this kind as more "serious" does not explain anything, however, but only begs the question of why it is handled as more "serious." Before this problem can be solved, it is likely that conduct itself will have to be understood in an entirely different way.¹⁴ At present, the relevance

of conduct is little more than common sense.

CONCLUSION

That crime and its seriousness may be explained with a theory of law is a departure from common sense. It is common sense that the very opposite is true, that law may be explained with crime and its seriousness, and with related conditions such as disorder, disruption, and disintegration. It is also common sense that rules of law ultimately decide cases in court, and that the winner is the party with the better case. But ideas of this kind are evaluative as well as factual, and have no place in the sociology of law. This is not to say that the problem of common sense is unique to the study of law. On the contrary, sociology is full of formulations that incorporate common sense. Consider, as further examples, the sociology of medicine, science, and art.

In the sociology of medicine, "health" and "illness" are generally understood in much the same way as they are understood by physicians, and so is the practice of medicine itself. Thus, "illness" is taken to be a need for care and treatment, as if this "need" were self-evident, a description rather than an evaluation (see, e.g., Mechanic, 1968; Jaco, 1972). What is more, this obscures variation in how people define and respond to "illness" (but see Freidson, 1970). Another strategy, by contrast, is to understand medicine as a quantitative variable,

¹³ A number of studies have found that people across the population and across societies generally rank the "seriousness" of hypothetical incidents in much the same order (see Gottfredson and Hindelang's references on p. 17). This does not necessarily mean, however, that these people would respond in the same way if they were the victims of incidents such as those described in the questionnaire, or even if they were merely present when such incidents occurred.

¹⁴ One possibility is to understand conduct as itself a location in social space that is subject to more or less law. For example, the conduct known as "vagrancy" may be understood as a place on the margin of social life, a location in "radial space" that is especially vulnerable to law directed from the center of social life, or "centrifugal law" (Black, 1976:49-53). Just as an unemployed and homeless man is

subject to more law—compared with an integrated man—if he is, say, drunk or violent, so are unemployment and homelessness subject to more law in their own right, apart from any other conduct. Similarly, "suicide," "desertion," and other forms of social withdrawal may be understood as movements away from the center of social life, vulnerable to law for that reason alone (Black, 1976:52-3). And "heresy" may be understood as a location in cultural space, vulnerable to law according to the same principle that explains why a drunk or violent person who is a member of an ethnic subculture is likely to receive more law than an equally drunk or violent person who is more conventional (Black, 1976:69-73). Without considerably more work, however, it is impossible to know how many facts this strategy will order, and in any case our map of social space will probably need more detail—even more dimensions—before much progress can be made.

measurable by the degree to which a particular condition is defined as worthy of medical attention, and by how much care and treatment it receives (see Black, 1978: 12-3). Just as the theory of law predicts and explains crime and its seriousness, then, it is possible to have a theory of medicine that predicts and explains illness and its seriousness. Until the sociology of medicine abandons the common sense of medicine, however, it can be little more than a branch of the medical profession.

Sociologists of science and art also have yet to escape the common sense of the people they study. Accordingly, in the sociology of science, "truth" and "knowledge" are taken as characteristics of ideas rather than evaluations of ideas. Although it is impossible to measure objectively the quality of an idea, sociologists continue to try, not realizing that all they can do is endorse the evaluations of one or another faction of science. Citations in the scientific literature are used as a measure of the quality of work, for example, and even to explain the success of scientists in their careers (e.g., Cole and Cole, 1973). An alternative is to understand an idea as itself a quantitative variable, its magnitude measurable by how people define and respond to it, whether by citations or other forms of recognition (see Black, 1978:15-6). It then becomes possible to have theory that predicts and explains who is defined as knowledgeable or ignorant, intelligent, stupid, or whatever. Similarly, sociologists of art could have theory that would predict and explain what is taken as "art." They could understand art as a quantitative variable, measured by the degree to which a creation is appreciated as beautiful or otherwise aesthetically important (see Black, 1978:19-20). Is it displayed in a museum or praised by critics? How much money is paid for it? Is it studied in universities? But sociologists have not tried to measure art as a variable. Instead they have participated in art criticism itself, as if beauty were a matter of fact (e.g., Shils, 1960; Jaeger and Selznick, 1964).

In sum, common sense in sociology results in a confusion of fact and value, so that evaluations appear as descriptions,

and justifications as explanations. It is possible, however, to transcend the discourse of everyday life, and to be scientific instead of practical. At its best, sociology has no common sense at all.

THEORY AND RESEARCH IN THE SOCIOLOGY OF LAW*

MICHAEL R. GOTTFREDSON

State University of New York, Albany

MICHAEL J. HINDELANG

*State University of New York, Albany**American Sociological Review* 1979, Vol. 44 (February):27-37

Black's (1979) comment, when read in conjunction with *The Behavior of Law* (Black, 1976), raises several questions pertaining to the scientific adequacy of his theory of law. This paper assesses Black's theory against two criteria of scientific adequacy: generality and falsifiability. Black (1979) rejects our use of victimization survey data to test his theory because these data do not allow a comparison of that conduct initially labelled as crime and that conduct not so labelled. Our interest was not in this first-stage labelling, but in the second-stage decision by victims to increase the quantity of law by calling the police, *given* that the respondent had labelled some behavior as a crime. Black argues against such second-stage tests of his theory and also argues that his theory must be viewed as valid only with respect to the initial labelling of conduct as illegal; as a result, all labelling decisions predicated on the initial labelling decision are beyond the province of his theory. We also note that the basis of Black's (1979) restriction of the generality of his theory is inconsistent with his original statement of the theory (Black, 1976) in which he uses results from victimization surveys (of the same kind he now argues are irrelevant to the theory) to support his theory. In addition, Black's (1979) criteria for data sufficient to test his theory reduce the potential for testing his theory. Finally, we discuss some issues regarding conduct and its seriousness as they relate to Black's theory.

Introduction

A sine qua non of scientific theory is that it be capable of empirical test and refutation. Scientific theories have other important characteristics as well; for example; they organize, predict, and explain a body of knowledge. Another desirable characteristic of scientific theory is generality; desirable in the sense that the theory ac-

count for as many aspects of the phenomenon of concern as possible. Furthermore, scientific theories are enhanced to the degree that they make explicit how the critical variables are to be operationalized.

Most of these qualities appear in *The Behavior of Law* (Black, 1976). As can be seen by reference to our paper (Gottfredson and Hindelang, 1979), researchers testing Black's theory need not rely solely on their own uncertain interpretations of abstract theoretical variables, but instead can rely primarily on Black's own exam-

ples; moreover, when Black (1976) cites empirical evidence to support his theoretical propositions, the character of this evidence reduces the ambiguity surrounding the use of theoretical constructs, thus facilitating tests of his theory.

In his comment on our empirical test of his theory, Black (1979) seems to have retreated from the positions that give his (Black, 1976) theory these virtues. If his arguments are accepted, his comment on our research has the effect of reducing the value of his theory in two important respects. Both its generality and the potential for unambiguous empirical test have been markedly reduced.

With respect to its generality, Black (1979) seems to have relegated much of what is typically regarded as within the province of the sociology of law to unimportance by focusing exclusively on the initial labelling of conduct as crime. The basis for this conclusion and some of the implications of Black's (1979) comment on this point will be the first focus of our discussion.

The second focus of our discussion revolves around the standards that Black invokes in judging our data, and the implications of accepting those standards for the falsifiability of his theory.

Finally, Black (1979) has argued that conduct and estimates of its seriousness cannot be the basis for useful theoretical constructs in the sociology of law. Contrary to the emphasis of Black's comment on our paper, the empirical validity of his propositions as revealed in our data may be judged apart from the validity and utility of consensually defined seriousness. We conclude with a discussion of these issues.

THE GENERALITY OF THE BEHAVIOR OF LAW

There can be little doubt that Black (1976) envisions his theory of law as being capable of explaining law in all settings at all times:

The quantity of law varies in time and space. It varies across the centuries, decades and years, months and days, even the hours of a day. It varies across societies, regions, communities, neighborhoods, families, and

relationships of every kind. . . . It varies across the world and its history. . . . All of this is the behavior of law, and it is possible to explain all of it. (Black, 1976:3-4)

With numerous examples, Black also is explicit concerning how the quantity of law, as he defines it (Black, 1976:2), can be measured:

A complaint to a legal official, for example, is more law than no complaint, whether it is a call to the police, a visit to a regulatory agency, or a lawsuit. Each is an increase in the quantity of law. (Black, 1976:3)

Black's theory of law aims to predict the quantity of law everywhere that it occurs, whether it be civil law, administrative law, or criminal law. And within the criminal law even at each stage of the criminal process:

The propositions address a wide range of legal variation, including, for example, variation in what is defined as illegal, who calls the police or brings a lawsuit, who wins in court, who appeals or wins a reversal. . . . (Black, 1976:ix)

More explicitly within the criminal law, Black argues that the victim's complaint, recognition of the complaint, arrest, indictment, prosecution, conviction, and punishment are all indicators of the quantity of law (Black, 1976:3). In fact, "[a]ny initiation, invocation, or application of law increases its quantity . . ." (Black, 1976:3). Thus, any time law is applied or invoked, Black asserts that his propositions account for it.

From the standpoint of those wishing to test Black's propositions empirically, it is necessary to make some judgment about precisely what Black means by his predictions about the quantity of law. Should these assertions about the quantity of law be read to imply that the relevant predictions are "proximally conditional," or are these predictions "only initially conditional"—only conditional on the behavior subject to the initial labelling as illegal? If they are meant to be "proximally conditional," then the researcher interested in testing Black's theory must assess the propositions in relation to a base of potential application of the law; that is, Black's propositions must be tested at a particular stage of the criminal

process, given that cases reached the immediately prior stage (e.g., who is charged with a crime by the prosecutor, given those arrested). For example, Black (1976:3) argues that "parole is less law" and that "a revocation of parole is more" law. If the propositions are meant to be "proximally conditional," then the relevant test of the propositions explaining release on parole must examine all those eligible for parole. Among those eligible for parole, those released on parole must be compared with those not released on parole. Similarly, the relevant test for explaining parole revocation is among parolees.

If, on the other hand, the assertions about the quantity of law are meant to be "only initially conditional," then the researcher must employ an entirely different strategy with respect to the basis for comparison. The relevant test would ignore previous applications of the law. Under the "only initially conditional" model each invocation of the law is viewed as being equally applicable to all similar behavior regardless of previous labelling decisions. Thus, for example, when Black (1976:3) argues that the propositions in his theory predict who will be convicted at a criminal trial, the relevant empirical test under the "only initially conditional" model would not be "among those tried," but rather "among all persons engaging in behavior that is subject to the initial labelling as illegal."¹

These alternative interpretations have major implications for the generality and the testability of Black's theory. In this respect, then, the basis for Black's rejection of the relevance of our recent examination of propositions found in *The Behavior of Law* is of considerable importance:

... because the incidents labelled as "crimes" for purposes of their study were selected by the respondents, variation in the

labelling process itself was completely obscured, making it impossible to test the theory of law with their data. (Black, 1979:19)

Leaving aside for the moment measurement problems in victimization surveys, what is critical about Black's observation is that the quantity of law is to be predicted under the "only initially conditional" rather than the "proximally conditional" model.

In our study, Black's theoretical propositions were examined in relation to the victim's decision to call the police, which is our indicator of the quantity of law. Although it is an important question, we did not study the victim's definition of behavior as criminal (as implied in Black, 1979), which we regard as an earlier and different indicator of the quantity of law. Similarly, we regard the decision by the police to arrest to be a later and different indicator of the quantity of law.

Using the "proximally conditional" model, we tested Black's theory with respect to calls to the police by studying how well his propositions predict calls to the police, *given* that the event was defined as a crime by the respondent. Black (1979) argues that because the first-stage data (the initial labelling of conduct as crime) are not available, the second-stage data (whether or not the crime was reported to the police) are irrelevant to his theory. Thus, Black (1979) argues against testing his theory under the "proximally conditional" model.

However, the "proximally conditional" model appears to be compatible with both the theory and the supporting research presented in *The Behavior of Law*. Consider, for example, the following passage:²

Thus, intimates are less likely to call the police about each other (see McIntyre, 1967:45; Block, 1974:560-561). *If they do*, the police are less likely to handle their problem as a crime (Black, 1970:740-741), and, in any case, they are less likely to make an arrest (Black, 1971:1097-1098). *If an intimate is arrested*, he is less likely to be prosecuted (Hall, 1952:318). (Black, 1976:42, emphases added)

Two aspects of this passage are worthy of note. First, Black supports his theoretic

¹ Rather than "among all persons engaging in behavior that is subject to the initial labelling as illegal," Black sometimes makes comparisons to the general population (for example, compare Black [1976] pages 31 and 18 to page 24). In the latter instance, Black's theory is comparable to labelling "theory" in its most characteristic form (e.g., Becker, 1963; Erickson, 1962).

² Similar examples are found throughout Black (1976, e.g., 17, 32, 64, 95, 114).

cal proposition with data he now claims are incapable of testing the theory. *The studies by Block (1974) and by McIntyre (1967) are analyses of reporting decisions by victims of crime as reflected in victimization surveys.* If Black can use findings from a victimization survey when they support his theory, then to be consistent, data from a conceptually identical study that do not support his theory cannot be deemed irrelevant.³ Otherwise, we are in the peculiar situation of determining the relevance of empirical proof on the basis of whether it does or does not support the theory.

If the Block and McIntyre studies are relevant to the theory, then, the "proximally conditional" model must be the correct one; their studies examine differences in calling the police, *given* that an event has been reported to survey interviewers (or, in Black's [1979] terms, given that the respondent has labelled the incident as "worthy of police attention"). But note that the quoted passage (Black, 1976:42) gives other strong support to the "proximally conditional" view. Black's prediction about arrest by the police is predicated on the fact that the police were called. And, the prosecution prediction is predicated on arrest.

In *The Behavior of Law*, Black states that his theory of law predicts the quantity

of law at every stage, from the initial definition of what is illegal, through calling the police, to arrest, incarceration, and release on parole (Black, 1976:ix). Each of these indicators of the quantity of law, he argues, is explained by propositions relating to stratification, morphology, culture, organization, and social control. Studies in the sociology of law have established that later stages of the criminal justice process in modern America depend largely upon input from earlier stages for the kinds of offenses elicited in victimization surveys. For example, although police and prosecutors can be proactive, much evidence indicates that they are principally reactive with respect to cases that serve as the basis for their decisions (LaFave, 1965; Newman, 1966; Remington et al., 1969; Dawson, 1969; Black and Reiss, 1970; Reiss, 1971; Hindelang and Gottfredson, 1976). Thus, from the initial labelling of conduct as crime to the termination of the criminal justice process, each stage depends primarily on the immediately prior stage for input; that is, the stages are heavily interdependent for the types of offenses studied in our paper.

According to Black's (1976) theory, the cases that do not proceed from one stage to the next are predictable from his propositions. For example, in the quoted passage above, Black (1976:42) argues that his propositions predict that intimates are less likely than strangers to report each other to the police (i.e., strangers disproportionately move forward in the criminal process).⁴ But among those intimates and strangers who do move forward in the process, the police are also less likely to handle complaints between intimates (than complaints between strangers) as crimes. Despite the biased selection from stage to stage, Black's (1976) theory states that the same propositions account for the quantity of law at later as well as at earlier stages. This is necessarily so because his theory (Black, 1976) purports to explain all of the behavior of law with the same set of propositions.

³ By conceptually identical, we mean general population surveys of the same kinds of criminal victimization, using similar measurement techniques. The single survey upon which both of the studies cited by Black are based is methodologically inferior to current victimization surveys in several respects (Hindelang, 1976: chap. 2). Furthermore, the principal methodological difference between the survey cited by Black to support his theory and the survey we used makes the survey data cited by Black less suitable by his own criteria. This earlier survey conducted for the President's Crime Commission (Bunis, 1967) used the "household-respondent" method rather than interviewing all eligible household members regarding the "screen" questions. It is known that the former method substantially undercounts victimizations of household members other than the household respondent (see Hindelang, 1976: chap. 3). That is, victimizations of household respondents (who differ demographically from other household members, e.g., the former are more often female) are overrepresented among victimizations elicited by the survey. Also, the Block (1974) data cited by Black (1976) use only assault victimizations, the crime most undercounted in victimization surveys.

⁴ Because Black often uses phrases like "less likely" without completing the phrase (e.g., "intimates are less likely than nonintimates . . ."), his precise meaning often (as in this quote) can only be inferred from the data cited to support his statement.

It is certainly worthy of note, therefore, that Black's (1979) comment places stringent limitations on the generality of his theory by requiring an "only initially conditional" rather than a "proximally conditional" test. By rejecting the "proximally conditional" model, Black (1979) argues, in effect, that a call to the police is not an increase in the quantity of law over the victim's initial definition of conduct as illegal. To be consistent then, Black must also argue that, *given conviction*, incarceration is not more law than is a disposition not involving incarceration (e.g., fine or probation); that, *given prosecution*, conviction is not more law than acquittal; that, *given arrest*, prosecution is not more law than dismissal of charges; that, *given a complaint*, arrest is not more law than failure to arrest. Rather, Black (1979) argues that his theory can only be tested by using as a base for comparison all identical conduct subject to the initial definition as illegal. Thus, a test of the predictive validity of his theory with respect to conviction (to be consistent with the basis used to reject our test of his theory) must be of the form: How do the "location and direction in social space" of persons convicted for engaging in particular conduct compare with the "location and direction in social space" of persons engaging in identical conduct, regardless of whether the latter are prosecuted, arrested, reported to the police, or even regardless of whether their conduct was initially defined as illegal? In Black's (1979:22) words:

Similar processes of selection—according to the same principles—occur at other stages of the criminal process, such as in the charging and prosecuting of offenses against persons accused of crimes, and, in fact, wherever else cases of any kind are labelled according to legal criteria. If we are to learn how these labels are applied, then, we must examine all of the cases involving the same conduct, regardless of how they have been classified by people in everyday life.

Thus, apparently, Black (1979) no longer purports, as he does in *The Behavior of Law* (1976: e.g., 17, 32, 42, 64, 95, 114), that his theory explains increments in the quantity of law from one stage of criminal processing to another. Moreover, much of the empirical evidence he cites in support

of his theory (Black, 1976), is, according to Black (1979), irrelevant to his theory. Not only are the victimization studies of Block (1974) and McIntyre (1967) deemed irrelevant by his current stance, but so is much other evidence as well. This is so because much of the evidence cited by Black (1976) rests on the "proximally conditional" model. Thus, for example, in support of his propositions relating to organization, Black (1976:95) notes that

... theft from a department store by a customer or an employee has a conviction rate of nearly 100 percent of the cases prosecuted (Cameron, 1964:142; Robin, 1967:696). But for auto theft—almost always a crime against an individual—this rate is only a little over 50 percent (U.S. Federal Bureau of Investigation, 1974:20).

The base of the rate for prosecutions of shoplifting is "persons charged" with this offense, not persons engaging in similar conduct but not charged. Under the "only initially conditional" model that Black now views as appropriate, the base of the shoplifting percentage should be all persons engaging in shoplifting. The evidence cited by Black (1976), suggests that his theory views conviction as an increment in the quantity of law in relation to prosecution, but Black (1979) substantially reduces the scope of his theory by maintaining now that such "proximally conditional" tests are irrelevant to his theory.

Paradoxically, while seeming to dismiss the relevance of our study to his theory of law, Black (1979) again poses the question that our study was designed to address. He argues that our data reflect only incidents deemed "worthy of police attention" by the respondents. He then notes that "... it should be realized that simply because a person considers an incident worthy of police attention does not mean the police will actually be called" (Black, 1979: fn. 3). This is precisely what our study was about; among those incidents deemed "worthy of police attention," what predicts calls to the police? The question Black must address (and fails to address in his comment) is that if his theory explains *all* law, why is it unable to explain this fundamental increase in the quantity of law? Either Black must argue that calling the police, *given* the definition

of conduct as illegal, is not an increase in the quantity of law (and similarly, conviction, *given* prosecution, is not an increase in the quantity of law), or he must accept, at least in principle, such "proximally conditional" studies as relevant to his theory.

FALSIFIABILITY AND THE BEHAVIOR OF LAW

If one accepts all of Black's (1979) arguments with respect to our test of his theory, not only is the generality of his theory markedly restricted but so too is its potential for unambiguous empirical test. It should be stressed that Black's (1979) entire line of argument with respect to the initial labelling of behavior as crime is not relevant to our "proximally conditional" test of his theory as stated in *The Behavior of Law*.⁵ But because it raises fundamen-

tal questions about the testability of his theory, and, more generally, about empirical analyses of the labelling of behavior as criminal, it merits discussion.

Given the arguments in Black's comment, it would seem useful to pose the question: How is his theory that the labelling of crime "varies with its location and direction of social space" (Black, 1979:19) to be assessed? Black suggests (1979:fn. 7) that "data based on direct and unobtrusive observation would therefore appear to be the most reliable way to test the theory of law. . . ."

We see three insurmountable problems that Black (1979) erects to empirical observational tests of how labelling of events as crime varies throughout the social structure. First, Black (1979) insists (by inference from the first part of our paper) that a relevant test of his theory is of the form: Among *all* behavior, what behaviors are labelled as illegal and how is this labelling distributed in social space? Using observational methods now available, it is virtually impossible from a practical standpoint to observe an unbiased sample of all behavior, because so much of it occurs in private settings. It is unlikely that rates of refusal to permit observers into homes, bedrooms, offices, factories, and schools will be randomly distributed throughout the social structure; also, much of the behavior of organized crime figures, street criminals, and corporate executives is likely to be shielded from view. Second, because Black (1979:20) argues that "the concept of 'crime' is inherently vague" and that the social construction of behavior as "crime" is not merely a description but is always an evaluation (and because Black rejects evaluations as inappropriate for testing his theory in this context), an observer's judgment about behavior would be biased by the observer's location in social space.⁶ Third, even if the observer could

⁵ Contrary to Black's (1979:21) assertion, we did not use victimization surveys to test the initial labelling of behavior as crime. Hence, his discussion and critique of victimization surveys for that purpose are technically irrelevant. However, two general points about these surveys need to be noted briefly. First, Black (1979:21) claims that we "apparently did not recognize the broader implications of [undercounting of victimizations] for the validity of [our] study." In earlier work, we (Hindelang, 1976:12-76, 415; Hindelang et al., 1978: chap. 10; Gottfredson and Hindelang, 1977; Garofalo and Hindelang, 1977; Hindelang, 1978) and others (Penick and Owens, 1977; Sparks et al., 1977) have discussed the limitations and biases in victimization surveys. In our paper, we noted the existence and direction of the only bias of which we are aware that bears on the portions of Black's theory we did test. Although we believe that there is ample evidence of measurement error in victimization surveys, particularly in estimating absolute levels of victimization, there are few biases that have been identified that bear on relationships of the kind we used to test Black's (1976) theory. Certainly we are aware of no biases in victimization surveys of the magnitude required to change the overall picture portrayed by the data in our paper. Second, Black (1979:20) leaves the impression that the victimization screen questions primarily used legal jargon such as "rob" and "mugging." Although such terms were used, most screen questions used everyday language such as "take . . . by using force," "beat you up," "threaten you," and "Were you knifed, shot at or attacked?" Third, the sentence "Now, I'd like to ask some questions about crime," only preceded the interview of a single member of each household (the "household respondent"); fewer than half of the persons interviewed were household respondents.

⁶ In Black's (1979:20) words "what is a 'crime' to one person may not be to another. . . ." We presume that because Black's theory is said to predict biases in victimization surveys, then it must also predict biases in observational studies. For example, in an observational study of police arrest decisions, an observer's evaluations of behavior as criminal would be predictable from the observer's location in social space.

be absolutely unbiased and entirely objective, testing how the labelling of behavior as crime is distributed throughout social space could not be determined by observation alone. How can an unobtrusive observer (required by Black, 1979: fn. 7) determine that someone else has labelled an observed event as a crime? Black (1979: fn. 7) rejects social surveys for this purpose. He also rejects behavioral indicators such as calling the police, because an incident labelled as crime (i.e., "worthy of police attention") does not necessarily result in a call to the police (1979: fn. 3). What Black views as the critical aspect of his theory, the initial labelling of behavior as crime by individuals, is a cognitive process. And cognitive processes cannot be observed directly.⁷ Hence, neither observational methods nor any other empirical method can provide data that would meet all of Black's (1979) criteria for adequacy.

THE SERIOUSNESS OF CRIME

In *The Behavior of Law*, Black (1976) is not consistent regarding the relevance of conduct to his theory. In most of the explicit discussions of the relevance of conduct to his theory, Black indicates that it is irrelevant (i.e., is permitted to vary freely), while occasionally he indicates that variation in conduct is relevant (i.e., need be "held constant" in testing propositions).⁸ Thus, for example, on the one hand Black writes:

We recognize that part of Black's (1979) objection to surveys derives from his view that participants cannot report accurately on their own behavior. Surveys are subject to biases of this kind; in toto, however, they seem preferable (for the reasons outlined above) to observational studies for the problem of interest to us (calling the police.)

⁷ Black also ignores the following practical problems with using observational methods for this particular problem: (a) the tremendous cost, given the relative rarity of criminal behavior; (b) intra- and interobserver reliability; and (c) how the relevant independent variables could be measured using unobtrusive observational methods.

⁸ To confuse the matter even more, Black (1976:25, 28) often uses crime-specific examples (e.g., shoplifting and homicide) implying that research that holds conduct constant is relevant to the theory. At other times he discusses crime as if it were a unitary, undifferentiated phenomenon (e.g., Black, 1976:15, 17, 21).

It might be noted that these principles apply *whatever the actual behavior* of the lower ranks—whether for example it is more or less violent or predatory—since their conduct is more likely to be defined as illegal *no matter what they do*. (Black, 1976:31, emphases added)

Similarly, he argues:

The theory of law, however, predicts the same facts. But it explains these facts in a different way, without regard to the motivation or even the conduct of the deviant. . . . (Black, 1976:118, emphasis added)

On the other hand, however, Black writes:

It might be noted that comparisons such as these [studies of variation in punishment] should be made according to the offender's *actual conduct*, rather than according to the crime with which he is charged. . . . (Black, 1976:24, emphasis added)

Despite such inconsistency, however, the major thrust of *The Behavior of Law* is to consider variability in conduct to be virtually irrelevant. As we noted in our paper, at a minimum, Black (1976) must be interpreted as arguing that conduct is less important as a determinant of the quantity of law than are his five dimensions.

Because of Black's ambiguity on the issue of conduct, it was necessary to test his theory under two conditions: permitting conduct to vary and controlling for conduct in some way. Because of the large number of different "offender-conduct" variables in the data and the impossibility of investigating all of them simultaneously, the Sellin-Wolfgang (1964) scale was seen from an empirical point of view as a device useful for summarizing and scaling the offender's conduct along a single dimension, seriousness.⁹ From a

⁹ Our earlier research on reporting to the police, in which many individual elements relating to offender conduct were controlled, found generally that (with the exception of age) demographic characteristics of victims did not explain variations in reporting to the police. Rather, the victim's report of what happened during the event accounted for most of the explained variability (see Hindelang, 1976:chap.14; Hindelang and Gottfredson, 1976). Thus, although our earlier research was not conceived of as a test of Black's theory and did not operationalize most of his dimensions, that research indicated that offender conduct and harm to the victim, measured directly from victims' reports rather than indirectly with Sellin-

theoretical point of view, seriousness (i.e., harm to the victim) was seen as a dimension likely to affect the victim's belief that the conduct demands invocation of state social control mechanisms.

The aspects of victimization that are scaled in the Sellin-Wolfgang weighting system clearly reflect variations in conduct and its consequences that occur during victimization. We analyzed our tables both controlling for, and ignoring, variations in Sellin-Wolfgang scale scores in order to accommodate Black's (1976) inconsistency with respect to this issue. If variation in Sellin-Wolfgang scale scores is deemed to be irrelevant to Black's propositions, then the validity of Black's propositions should be assessed by collapsing across the rows in our tables; if conduct must be controlled, the data should be examined within rows. *Either way Black's (1976) propositions find little support in our data.*

We take seriousness as an indicator of variations in offender conduct and in its consequences to the victim. Black (1979) argues that whether the offender had a weapon, whether the victim was hospitalized, whether the victim was killed, and whether items of large or small value were stolen from the victim, constitute primarily evaluations rather than descriptions of what transpired. Certainly, we do not deny that what happens during an event must be interpreted, or that the seriousness of the consequences of behavior is a matter of judgment. We accept victims' descriptions of the elements scored in the Sellin-Wolfgang procedure as indicators of what happened during the event. We also accept the consensually validated agreement of Sellin and Wolfgang's subjects that, for example, homicide is more serious than hospitalization.¹⁰ Certainly, the resultant

seriousness-scale scores are not error free. But if the error variation is large relative to the true variation—that is, if our indicator is a poor one—why do the seriousness-scale scores do so much better than Black's dimensions in explaining calls to the police?

It is informative to follow the chain of reasoning that Black uses to dismiss our finding that seriousness is related to calls to the police.¹¹ Black (1979:19) first asserts that "... 'crime' and its 'seriousness' are expressions of law itself ..." and, next, that "... 'crime' is an incident worthy of police attention." He concludes (Black, 1979:20) that we have argued that "... 'crime' itself explains why people call the police. ..." Because Black (1979) defines crime as an incident worthy of police attention, his conclusion (which he attributes to us) translates into, "incidents worthy of police attention explain why people call the police." But Black (1979: fn. 3) also asserts that "... simply because a person considers an incident worthy of police attention does not mean the police will actually be called."¹² In this footnote, Black contradicts his textual assertion that calls to the police are explained by crime, a conclusion that he erroneously attributes to us.¹³ Although it

scores have two components: one descriptive (from the victims in our study) and the other evaluative (from Sellin and Wolfgang's independent sample of raters). Importantly, the evaluative component was derived independently of our survey respondents and their decisions to call the police.

¹¹ And the similar findings of others as well. See his (1979) footnote 8. The conclusions in the studies Black cites in this footnote may depend on whether or not seriousness was controlled. As noted above, our conclusions with respect to Black's (1976) propositions are the same, regardless of whether or not seriousness is controlled.

¹² As we noted above, apparently Black does not recognize that our research is an attempt to answer this very question: Among events "considered worthy of police attention" what differentiates those reported from those not reported to the police?

¹³ Although Black implies throughout his comment that there is a necessary (even a definitional) relationship between seriousness in its conventional sense and calls to the police, it should be obvious that there is no necessary relationship between the two. Apart from offender conduct and its consequences to victims, there are many contingencies that affect the likelihood that a victim will call the police: insurance policies may require reporting to the police as a condition for processing claims; hos-

Wolfgang seriousness scores, were predictive of calling the police. Thus, conduct, independent of assessments of its seriousness, predicts calls to the police.

¹⁰ Black (1979:19) strongly overstates his case when he asserts that we "... mistake a variable that requires explanation for one that provides it" and that (Black, 1979:abstract) we "... mistake an evaluation for a description." What Black fails to recognize is that our resultant Sellin-Wolfgang scale

impedes effective communication, we have no quarrel with Black's choosing to make words mean what he wants them to mean rather than adhering to their conventional usage, as long as he does not invoke his meaning to explain our words.¹⁴

On a related issue, Black (1979) argues, and we agree, that the Sellin-Wolfgang seriousness-scaling procedure did not permit the social conditions under which their crime vignettes occurred to vary systematically; hence, the resultant seriousness-scale scores are not sensitive to variation in the social conditions under which crimes occur. For Black, this is critical, because his conception of seriousness depends upon the social conditions under which crimes occur.¹⁵ But when the

pitals, doctors, and restitution and compensation programs may require police notification as a prerequisite for dispensing services and benefits to victims; property that is licensed and/or has serial numbers may be reported when stolen because there is some chance of tracing such property; if the victim can offer the police a description of the offender or the offender's vehicle, the crime may be more likely to be reported than if the victim cannot; if the victim was engaged in illegal or deviant conduct (e.g., visiting a house of prostitution or engaging in illegal gambling) the victim may be less likely to report a crime to the police; fear of reprisal or fear of increasing familial discord may inhibit reporting to the police; mistrust or fear of the police may decrease the likelihood of a report to the police; embarrassment at having been victimized and at having to relate the story of the crime to the police may discourage reporting to the police; and the victim may believe that the physical, property, or psychological damage that has been done by the victimization cannot be repaired by calling the police. Such eventualities may be directly or inversely related to seriousness-scale scores or they may be unrelated to these scores. Certainly, most observers would not regard these as aspects of seriousness.

¹⁴ Another example of this phenomenon is his quote of our fn. 5 (Black, 1979:21): "This bias probably works against Black's hypothesis [about the effect of intimacy on the labelling of crime]." The appropriate bracketed phrase should be "about the effect of intimacy on the victim's decision to report the incident to the police." Otherwise, the reader is misled into believing that our study was about the initial labelling of conduct as crime, rather than about calls to the police.

¹⁵ Black (1979) points out that Rossi et al. (1974) did permit the social conditions to vary in their study of the relative seriousness of events and that such conditions were related to the seriousness ranks. Had we used such a scale as an indicator of seriousness, rather than a scale that did not permit these

interest centers on conduct and its consequences to the victim, such a procedure is preferable. It should be obvious that if Black's position is correct and the social conditions under which crime occurs are all-important, there should be no relationship between a seriousness measure based principally on conduct (i.e., not on the conditions under which it occurs) and victims' reports to the police (or any other quantity of law). Furthermore, if Black is correct, his dimensions, which incorporate such variables as the victim-offender relationship and the relative social ranks of the victim and the offender, should be predictive of reporting to the police. Our data show that the measure of conduct and its consequences to the victim employed in our study was more strongly related to the quantity of law than were Black's dimensions. Therefore, although what is regarded as serious depends, in part, on the social conditions under which it occurs, it depends in large part on conduct as well.¹⁶

Finally, regardless of the adequacy of our measure of seriousness, the fact remains that, in our data, Black's propositions as we have operationalized them, generally do not account for a substantial amount of variability in calls to the police. Black (1979:21) maintains that his "theory of law predicts and explains common sense . . .," which is what he construes our seriousness explanation of calls to the police to be. But if Black's theory of law predicts such "common sense," then his dimensions should have been able to account for at least as much variance as that accounted for by Sellin-Wolfgang seriousness scores. Black's comment fails to offer compelling justification, much less evidence, for why they do not.¹⁷

conditions to influence the seriousness scores, and analyzed Black's propositions within categories of these social condition-relevant scores, Black's dimensions would have been confounded with the seriousness scores.

¹⁶ Others have found that conduct and its consequences to victims can be useful in explaining variation in the quantity of law. For example, the first proposition of Jerome Hall's (1952:318) theory of the rate of prosecution of known offenders is that "the rate of prosecution varies directly in proportion to the gravity of harm."

¹⁷ For our part, and to aid any future research, we

CONCLUSION

Black dismisses our work because it does not comport with his notion of what are the desirable properties of science. Labelling and dismissing theoretical positions that are not compatible with one's own as "nothing more than common sense" is simply not persuasive. Common sense itself is a variable aspect of reality. For example, *The Behavior of Law* (1976) has been criticized on this ground:

Black's propositions are somewhat self-evident: nothing more and nothing less than systematized common sense. But there are some problems concerning the *explanatory* power of this systematized common sense. (Eder, 1977:137)

Clearly, something more is required as the basis for judging the adequacy of scientific theories. In the introduction we enumerated several criteria for scientific theory. Many of these are embodied in *The Behavior of Law*. It would be unfortunate if Black's (1979) clarification of the theory were to have the effects of banishing his theory as originally stated from the jurisdiction of empirical test and substantially reducing its generality. When viewed as a "proximally conditional" model, Black's (1976) theory is extremely general and it deserves to be tested extensively and refined on the basis of research findings.

Ultimately, the most important criterion for a scientific theory is that it be compatible with the facts. Otherwise, what does it mean to have sociological theory "in its pure form" (Black, 1979:19) if it does not agree with the best available evidence?

ERRATUM

An error occurred in Jeffrey C. Alexander's article, "Formal and Substantive Voluntarism" (*ASR* April, 1978). On page 182 (eleventh line from the bottom, left column), *international* should read *intentional*.

MANUSCRIPTS FOR THE ASA ROSE SOCIOLOGY SERIES

Manuscripts (100 to 300 typed pages) are solicited for publication in the *ASA Arnold and Caroline Rose Monograph Series*. The Series welcomes a variety of types of sociological work—qualitative or quantitative empirical studies, and theoretical or methodological treatises. An author should submit three copies of a manuscript for consideration to the Series Editor, Professor Robin M. Williams, Jr., Department of Sociology, Cornell University, Ithaca, New York 14853.

CLASS AS CONCEIVED BY MARX AND DAHRENDORF: EFFECTS ON INCOME INEQUALITY AND POLITICS IN THE UNITED STATES AND GREAT BRITAIN*

American Sociological Review 1979, Vol. 44 (February):38-58

The class theories of Karl Marx and Ralf Dahrendorf, although subject to much theoretical analysis, largely have been ignored in the dominant lines of quantitative research on status attainment and the political consequences of social stratification. This paper attempts to bridge this gap by drawing out some of the implications of Marx's ownership of the means of production and Dahrendorf's authority for both income inequality and politics, by evaluating these implications empirically and by showing how these conceptions of class can be incorporated into the dominant Blau-Duncan model of status attainment. Using survey data from large national samples in the United States and Great Britain, we show that both Marx's and Dahrendorf's class models have important implications for men's income, increasing by almost half the variance explained by the conventional Blau-Duncan model. The income of American women, in contrast, is little influenced by class and this explains a substantial part of the male-female income gap. As Marx, Dahrendorf, and others predicted, class position has a stronger impact on class identification and politics in Great Britain than in the United States. An analysis of the transfer of class position from one generation to the next in Britain suggests the existence of two overlapping but distinct stratification systems, one a class system rooted in ownership of the means of production and authority, and the other a status system based on education and occupational status.

Dominated by the Blau-Duncan (1967) paradigm, quantitative research on stratification has focused narrowly on education and occupational status while generally ignoring more conflict oriented aspects of stratification stemming from the hierarchical organization of work. In

this paper we suggest that the conventional paradigm be extended to include two additional dimensions of stratification, each the focus of a major theoretical tradition—Karl Marx's *ownership of the means of production* and Ralf Dahrendorf's exercise of *authority in the workplace*. Although Marx's and Dahrendorf's class theories have been subject to much theoretical analysis,¹ there has been little attempt to assess their empirical adequacy.² Our general aim is to attempt to

Revised version of a paper presented at the annual meeting of the American Sociological Association, Chicago, 1977. We gratefully acknowledge financial assistance from the National Institute of Mental Health (Grant No. R01-MH26606-01). We thank Peter M. Blau, Lewis A. Coser, Ralf Dahrendorf, Otis Dudley Duncan, Anthony Giddens, Patty Gwartney-Gibb, Lawrence E. Hazelrigg, F. Lancaster Jones, Bernice A. Pescosolido, Patricia A. Roos, John D. Stephens, Arthur L. Stinchcombe, J. L. P. Thompson, Donald J. Treiman, R. Stephen Warner, Erik Olin Wright, and the anonymous referees of this *Review* for their helpful comments, and the National Opinion Research Center and the Inter-University Consortium for Political Research for making the data available. Sole responsibility for any errors rests with the authors.

¹ Theoretical critiques of Marx are too numerous to mention here; for Dahrendorf see Giddens, 1973; Hazelrigg, 1972; Turner, 1973; Weingart, 1969.

² Although numerous empirical studies have been based on Marx's class theory, to our knowledge only Wright and Perrone's (1977) work, which we discuss later, measures class in a way which is at all close to Marx's definition of it. Two empirical studies of Dahrendorf's theory have been attempted. One used occupation as a surrogate for authority (Lopreato, 1968), a procedure which we view as inappropriate (see Table 2), and the second dealt with topics different from those we discuss here (Fox et al., 1977).

bridge this gap, demonstrating the empirical importance of these class models and integrating them into the established tradition of quantitative research. Specifically, we first propose operationalizations of Marx's and Dahrendorf's concepts of class and draw out their theoretical and empirical implications for each other and for the Blau-Duncan status model. Second, we consider the class bases of income inequality and propose a modification of Dahrendorf's theory, suggesting that there are more authority classes than he envisioned. We then test Marx's, Dahrendorf's and our own predictions about income inequality on American and British data, considering men and women separately in the United States. Third, we test Marx's and Dahrendorf's prediction that the political consequences of class position are more important in Britain than in the U.S. Fourth, we use the British data to investigate the extent to which a father's class position as defined by Marx and Dahrendorf influences his son's attainments. We conclude that there are two distinct stratification systems in modern society, one the familiar status system centering on education and occupational status and the other a class system rooted in ownership of the means of production and authority.

THEORETICAL BACKGROUND

The Marxian Class Model

Marx distinguishes one class from another on the basis of two criteria, ownership of the means of production and purchase of the labor power of others. He defines three classes in modern bourgeois society. *Capitalists* own the means of production and purchase the labor power of others; *workers* neither own the means of production nor purchase the labor power of others but instead sell their own labor power; and the minor and transitional class of the *petite bourgeoisie* owns the means of production but does not purchase labor power.³ In a modern econ-

omy, Marx's criterion of ownership of the means of production may reasonably be expanded to include all forms of control of the means of production, whether they stem from legal ownership or formal control. Thus we include in the capitalist class managing directors who control but do not own the means of production since in practice they have effective control over their firms, can use them to further their own interests, and often own some stock in them. Many neo-Marxists argue that managing directors stand in a similar structural, if not legal, relation to the means of production and share many interests in common with the capitalist class (e.g., Baran and Sweezy, 1966; Domhoff, 1967; Kolko, 1962; Mills, 1957; Nichols, 1969; Zeitlin, 1974). For terminological simplicity we will refer to both owners and managing directors as "controlling the means of production."

As Marx (1852:515-6) conceives them, objective classes necessarily have conflicting interests by virtue of the exploitative nature of class relations but class members may or may not be subjectively aware that they share common interests "in hostile opposition" to those of another class, whence the distinction between class "in itself" and class "for itself."

Dahrendorf's Class Model

In Dahrendorf's (1959:166-74) analysis, classes are distinguished on the basis of their relations to authority. Members of the *command class*⁴ exercise authority,

not purchase labor power, as do Wright and Perrone (1977). While the difference between, for example, a self-employed plumber who works alone (*petit bourgeois*) and one who also has an assistant (*capitalist*) may seem slight, the empirical evidence indicates that there are noticeable differences particularly with regard to income. Other transitional classes from the earlier feudal epoch are land owners and peasants (Marx, 1852:517-9; Marx and Engels, 1932). Since these classes constitute such a small proportion of the population of modern industrial societies, we ignore them here. Elsewhere (Robinson, 1978; forthcoming), we have treated them in detail.

⁴ In our use of the labels, command and obey class, we follow Lopreato (1968). Dahrendorf does not label his classes.

³ Although Marx never defines the *petite bourgeoisie* as anything but smaller capitalists (Marx and Engels, 1848:25), it seems reasonable to define them as owners of the means of production who do

regardless of whether they are subject to it themselves; i.e., they have subordinates in the workplace; *obey class* members are subject to the authority of others and exercise none themselves, i.e., someone supervises them at work and they do not supervise anyone;⁵ and individuals in the small *classless* group neither exercise authority nor are subject to it, i.e., they work on their own.⁶ For Dahrendorf, as for Marx, class relations inherently involve conflicting interests, the command class having an interest in maintaining the authority structure and the obey class having an interest in overthrowing it. However interests may be only latent (more or less unconscious) or they may be manifest (conscious), in which case class members may mobilize around them (Dahrendorf, 1959:174-9).

Differences between Marx's and Dahrendorf's Class Models

Dahrendorf's concept of class is quite different from Marx's, as can be seen in Table 1. Marx's model stresses the *control* dimension of hierarchical position in the workplace while Dahrendorf's emphasizes the *authority* dimension, as we shall call them.⁷ By comparing Panels A and B, one can see that Marx's distinction between capitalists and workers is lost within Dahrendorf's command class; similarly Dahrendorf's distinction between command and obey classes is lost within

Marx's worker class. Marx, focusing on the top of the organizational hierarchy, asks whether someone is at the very top or is, instead, subject to a boss's control. Dahrendorf, focusing on the bottom of the organizational hierarchy, asks whether someone is at the very bottom, with no authority whatsoever or has, instead, at least one subordinate. Each uses the other's criterion only to separate out a marginal class which Marx calls the *petite bourgeoisie* and Dahrendorf defines as *classless*. The result is that Marx misses what is for Dahrendorf the key class boundary while Dahrendorf misses what is for Marx the key boundary. We will show that Marx's and Dahrendorf's models are statistically as well as theoretically distinct and that they usually have independent, and sometimes quite different, effects on the various dependent variables we consider.

Wright and Perrone's "Marxist Class Categories"

Wright and Perrone (1977) have recently proposed what they claim is an extension of the traditional Marxian class model by inserting a "manager" group between the capitalist and worker classes (see also Wright, 1976). Their managers are that subgroup of the worker class which exercises authority over others (see Table 1, Panel A, note a). This conceptualization is quite different from Marx's own analysis, since he does not see authority relations as constituting a basis for class conflict within the worker class any more than he sees income or occupational differences as constituting such a basis. In our view, Wright and Perrone's classification should be regarded as one way of combining the traditional Marxian model with Dahrendorf's model based on authority, rather than as an extension of Marx's model, and we will show that its effectiveness in explaining income and attitudes depends as much on Dahrendorf's authority as on Marx's control or ownership. The capitalist and *petit bourgeois* classes in Wright and Perrone's scheme are exactly Marx's; their sole modification is to divide the worker class in a way that corresponds precisely to

⁵ Dahrendorf (1959:256, 262, 287) notes that some positions, such as foreman and bureaucrat, are especially difficult to classify, but after some discussion handles them as we have.

⁶ For Dahrendorf (1959:198), all "imperatively coordinated associations" (e.g., the family, unions, sports clubs) are characterized by two authority classes, a position which has generated considerable criticism (e.g., Giddens, 1973:73). However, he does mention that authority relations in industrial production, which we here consider, tend to overshadow the authority relations of other associations since they occupy so large a space in people's lives (1959:142-3). Dahrendorf (1967) has considered some objections to his original formulation but these do not affect the basic scheme.

⁷ Following Marx, we operationalize the control dimension as a dichotomy. Although dichotomous for Dahrendorf, the authority dimension is illustrated as a trichotomy for comparison with our modification of his theory (Panel C), which is described later.

Table 1. Operationalization of Class as Conceived by Marx and Dahrendorf, and Improved Dahrendorf Model*

	Authority in the workplace		
	Exercises authority over others		Does not exercise authority
	(two or more levels of subordinates or employees)	(one level of subordinates or employees)	(no subordinates or employees)
Control of the means of production			
<i>Panel A. Marx</i>			
Controls the means of production (no supervisor or employer)	<i>capitalist</i>	<i>capitalist</i>	<i>petit bourgeois</i>
Does not control the means of production (has supervisor or employer)	<i>worker^a</i>	<i>worker^a</i>	<i>worker</i>
<i>Panel B. Dahrendorf</i>			
Controls the means of production (no supervisor or employer)	<i>command</i>	<i>command</i>	<i>classless</i>
Does not control the means of production (has supervisor or employer)	<i>command</i>	<i>command</i>	<i>obey</i>
<i>Panel C. Improved Dahrendorf</i>			
Controls the means of production (no supervisor or employer)	<i>upper command</i>	<i>lower command</i>	<i>classless</i>
Does not control the means of production (has supervisor or employer)	<i>upper command</i>	<i>lower command</i>	<i>obey</i>

* Categories of the variables used in operationalizing the class models (see note 15) are given in parentheses.

^a Manager group by Wright and Perrone's (1977) definition.

Dahrendorf's distinction between the command and obey classes of industry. Using both Marx's and Dahrendorf's conceptions of class leads to *exactly* the same division of the population; there is no class distinguished using Wright and Perrone's scheme that could not be distinguished with Marx and Dahrendorf combined. Such alternative parameterizations necessarily predict the same variance in other variables and so cannot be distinguished empirically on that basis.⁸ However, we will show that capitalists have high incomes *not only* because they own the means of production but also because they exercise authority. The true effects of owning the means of production can only be discerned by controlling (in the usual statistical sense) for authority by making ownership one variable and authority a second variable and using standard multivariate techniques for separating their effects. Wright and Perrone's typology does not lend itself to such techniques; they leave themselves with no

practical way of discovering the effects of control of the means of production, Marx's key theoretical variable, apart from the effects of authority. In contrast, our approach treats Marx's control of the means of production and Dahrendorf's authority as distinct aspects of the hierarchical organization of work and determines the effects of these relative to each other and to the variables of the Blau-Duncan model.

Class and Status Models of Stratification

The originators of the Blau-Duncan status model began with the assumption that "a fundamental trend toward expanding universalism characterizes industrial society" (Blau and Duncan, 1967:429-30), and that the rate of social mobility is generally so high in modern societies, and social groupings so transitory, that belonging to particular groups ceases to have much meaning to the individuals who are temporarily in them (Goldthorpe, 1976). There are no clearly defined classes with opposing interests, as with Marx and Dahrendorf, but rather a "socioeconomic" continuum on which one can rank individuals. The measures of occupational

⁸ Both must be implemented by three distinct dummy variables (or the equivalent), e.g., for Wright and Perrone, capitalist, manager, and petite bourgeoisie; and for Marx and Dahrendorf, capitalist, command class, and petite bourgeoisie.

standing used in this tradition assume a graduated continuum with no clear discontinuities (Duncan, 1961; Treiman, 1977); none of them comes close to measuring class in the categorical sense which it is traditionally given by Marx and most European sociologists. In a manner which is quite compatible with, and offers a reasonable extension of, Blau and Duncan's analysis, the flourishing human capital tradition in economics offers an analysis of education and training which also assumes relatively open, universalistic competition and a relatively continuous distribution of education and skills without clear boundaries or sharp discontinuities (e.g., Becker, 1965; Mincer, 1974).

Although it is often assumed that occupational standing and class are virtually identical, in fact there is little overlap between them, as both Marx (1893:862-3) and Dahrendorf (1959:138-40) stress. Occupations may be performed in a variety of class contexts. Lawyers, plumbers, or cooks, to name only a few examples, may work on their own account and hire assistants (and so be capitalists in the command class), or may work for a large company without any subordinates under them (and so be workers in the obey class), or may work for a large company and have subordinates (and so be workers in the command class), or may work alone on their own account (and so be petit bourgeois and classless). There is equally little reason for occupations with high status or prestige to be restricted to higher class positions, or for occupations with low status to appear only in lower class positions. We will show that in both the U.S. and Great Britain the actual correlations between class position and occupational status are distinctly modest.

Blau and Duncan's model and the human capital tradition have recently come under considerable criticism for ignoring the inheritance of property, various ascriptive elements in the class system, and conflict generally (Atkinson, 1975; Burawoy, 1977; Crowder, 1974:37; Doeringer and Piore, 1971; Giddens, 1973:19-20; Sahota, 1978:17-9; see, however, Griliches, 1977; Kelley, 1978). In fact, analysts in both the Blau-Duncan and

conflict traditions tend to deal only with their school's model of stratification and to ignore other models. Yet there is no theoretical justification or empirical necessity to take such one-sided views. Although all capitalists, for example, have many things in common, there is no reason for conflict theorists to ignore the clear differences between capitalists with high, middle, and low occupational status (e.g., owners of law firms, plumbing contractors, and hot dog stand owners). Nor is there any reason for researchers in the Blau-Duncan tradition to ignore the evident categorical differences between persons in the same occupation (e.g., plumbers who are employees vs. self-employed plumbers who hire other workers; engineers who supervise others vs. engineers at the bottom of the authority hierarchy).

Class and Income

Neither Marx nor Dahrendorf offers an explicit theory of the relation between class and income, a matter tangential to their primary concern with delineating the structural bases for political organization and mobilization. Marx (1893:862-3; 1902) insists that classes must not be equated with income groupings; they are not defined by either the "sources of revenue" or the "size of purses." Yet the exchange relationship between the capitalist and worker is inherently unequal and Marx (1849:31; 1867b:708-9, 715-6) expects the capitalist's profit generally to exceed the worker's wages in bourgeois society.⁹ Dahrendorf (1959:138-40) also views classes as "not based on the level or source of income" and, although he expects that class and income are highly correlated, is quite ambivalent about the existence of a causal connection between them. Thus, neither Marx nor Dahrendorf is particularly informative in analysing the class bases of income inequality.

⁹ Marx's concern with profits and wages is clearly more suited to an analysis of wealth than of income, although as Duncan (1968b:688) points out, there is a close relation between the two. Wealth put to use as capital generates income and income saved or invested contributes to wealth.

We would argue that there are, nonetheless, several reasons to expect that capitalists will be paid more than workers and command class members will be paid more than members of the obey class. First and most obviously, given that the upper classes in both Marx's and Dahrendorf's schemes have some power over the lower classes they should be able, within limits, to set the wages of those below them and presumably would set the wages of their employees and subordinates below their own. This argument holds especially for capitalists but should apply as well to some higher level managers and supervisors who may either directly determine their subordinates' wages or may indirectly influence these through evaluation of their job performance.

A second theory links class in Dahrendorf's sense with income. Lydall (1968:71, 125-7) argues that the higher salaries paid to supervisors are the result of the need of bureaucracies to fill positions of responsibility. Since supervisors are responsible for the actions of those below them, they have more "worry" than any of their subordinates, and worry is a cost for which they expect to be, and are, remunerated.

A third theory linking class and income, we suggest, may be derived from the marginal productivity theory of wages which essentially argues that employees are paid according to how much their work contributes to the firm's income (e.g., Rees, 1973:chaps. 4 and 5). In most circumstances variations in the ability and motivation of capitalists and supervisors will have more influence on output than similar variations among employees and subordinates. For example, when one employee does poorly that often has little effect on other employees' productivity, but when a boss or supervisor does poorly that will often affect the productivity of all of his or her subordinates. Thus total productivity depends more on bosses' and supervisors' performances than it does on ordinary workers' performances and, as Stinchcombe and Harris (1969) have shown, that implies higher marginal productivity. The economic argument then implies that capitalists and supervisors will in general receive higher pay than their employees or subordinates.

An improvement on Dahrendorf. These arguments suggest not only that capitalists and supervisors will be paid more than nonsupervisory employees, which is perfectly compatible with Marx's and Dahrendorf's analyses, but also that second line supervisors will be paid more than first line supervisors (and so on up the hierarchy), since they have more power to set salaries, more responsibility, and greater marginal productivity than their subordinates. This is not consistent with Dahrendorf's (1959:171) explicit insistence that there are no distinctions among supervisors (i.e., within the command class) and that "authority does not lend itself to the construction of a scale." But we suggest that authority is better conceptualized as a matter of degree and that Dahrendorf's theory should be modified to distinguish between the *lower command class* (who supervise only non-supervisory employees), the *higher command class* (who supervise the lower), and so on (see Table 1, Panel C). We call this the *continuous* version of authority and will show that this modification does noticeably better than Dahrendorf's original scheme in explaining income inequality and is equally effective in other contexts.¹⁰

DATA AND METHODS

NORC's General Social Surveys

The data are from the National Opinion Research Center's 1973, 1974 and 1976 General Social Surveys.¹¹ These are national samples of the noninstitutionalized population of the U.S., 18 years of age or older, conducted in the spring of each year. We have merged them into a single file. They are multistage probability samples to the block level with quotas based

¹⁰ Although he does not accept our modification (personal communication), it is consistent with Dahrendorf's basic logic. He argues that there are inherent differences in interests between the command and obey classes (e.g., between foremen and workers), and a similar analysis would suggest parallel differences between the higher and lower command classes (e.g., between managers and foremen), as indeed is implicit in his discussion of foremen and bureaucrats (1959:256, 262, 287).

¹¹ Our key variable was not asked in 1975.

on sex and age within blocks¹² (NORC, 1973; 1974; 1976). Analysis is confined to the 1,120 men and 598 women who were employed full-time and who responded to questions about their class position.¹³ We restrict our analysis to *full-time* employed persons to ensure comparability in our separate analyses of men and women since a disproportionate number of women who worked did so only part-time.¹⁴ The correlations, means, and standard deviations for the main variables used in the analysis are given in the appendix.

Measures

Marx and Dahrendorf. We determine class position on the basis of respondents' answers to questions on whether they have a boss or supervisor (i.e., the control dimension since those who have no supervisor control the means of production while those who are supervised do not) and the number of levels of subordinates below them (i.e., the authority dimension). This allows us to distinguish each of the cells in Figure 1 and so define our key variables.¹⁵ Distinguishing the pe-

tite bourgeoisie (or classless group in Dahrendorf's terminology) from other classes in these models added virtually nothing to the variance explained in income and attitudes. We therefore ignore this distinction in our analysis and group the petite bourgeoisie with the worker class in Marx's scheme—a classification quite consistent with Marx's expectation that this class would "sink gradually into the proletariat" in advanced capitalist societies (Marx and Engels, 1848:23), and which accords well with their actual income. In Dahrendorf's scheme classless individuals are grouped with the obey class, whom they closely resemble in income.¹⁶ In both Marx's and Dahrendorf's schemes we thus score the primary ruling classes (capitalist for Marx and command for Dahrendorf) one and the remaining classes zero. Alternative analyses in which the petite bourgeoisie was excluded from the sample altogether or treated as a separate class yielded results essentially identical to those reported below; details are available on request.

Nine-category dummy variable model. We also use a scheme which assigns a dummy variable to each possible combination of the two defining variables, i.e., each of the nine cells produced by cross-tabulating authority (three levels) by control (three levels).¹⁷ This captures all possible nonlinearities and interactions between the defining variables, and so gives the *maximum possible effect* that they can have on our dependent variables

¹² The 1976 survey is actually a split sample—one-half block quota and one-half full probability (NORC, 1976:91-4).

¹³ Eliminating the 187 respondents who did not reply to questions about their class position creates no bias. The distributions of education, occupation, and income are virtually identical for the full and restricted samples; in no category of these variables did the two samples differ by more than 0.8%.

¹⁴ Twenty-eight percent of employed women worked part-time compared with only 9% of employed men. Women worked an average of 35 hours per week while men averaged 43 hours per week.

¹⁵ The questions are:

1. Do you have a supervisor on your job to whom you are directly responsible?
 - 1a. Does that person have a supervisor on the job to whom he or she is directly responsible?
2. In your job, do you supervise anyone who is directly responsible to you?
 - 2a. Do any of *those* persons supervise anyone else? (NORC, 1976:80).

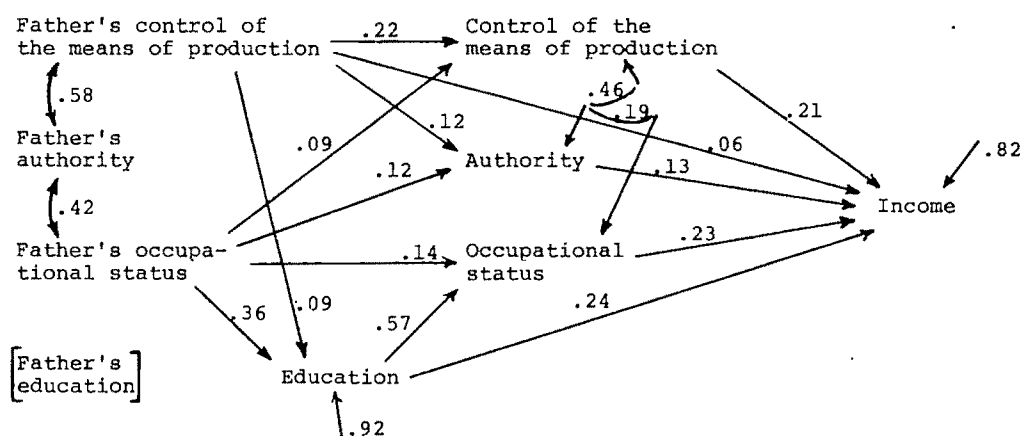

The questions appear to be adequate for preliminary operationalizations of Marx's and Dahrendorf's class schemes, although it must be recognized that they are subjective measures of the individual's position in the work hierarchy and may not always reflect objective position in the hierarchy. Teachers, for example, tended to respond that they supervised

others when apparently they were referring only to their students. Following Wright and Perrone's (1977) suggestion, we have reclassified them as supervising no one. Similarly, a small proportion of persons who responded that they have no supervisor may not actually control the means of production but may instead simply be autonomous workers. Another difficulty is that controllers in the private sector are not distinguished from those in the public sector, a distinction crucial to Marx's conception of class. We therefore have reclassified the very small number of government administrators in our sample as not controlling the means of production.

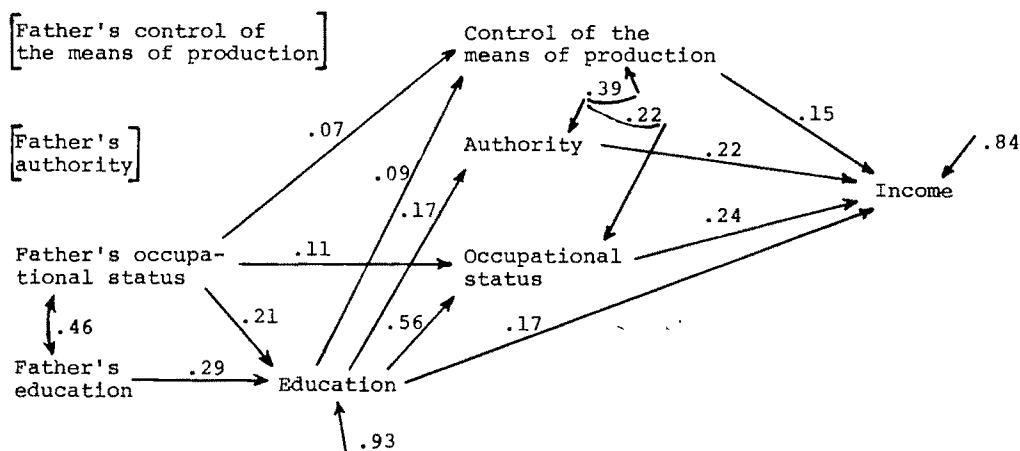

¹⁶ The mean income for men in the petite bourgeoisie (classless group) is \$13,043, compared with \$13,785 for workers and \$21,550 for capitalists in Marx's class model and \$12,147 for obey class members and \$17,476 for command class members in Dahrendorf's scheme.

¹⁷ Only eight dummy variables are used in the analysis, the ninth being implicit in the other eight.

GREAT BRITAIN

UNITED STATES

*Correlations less than .2 are not shown and paths which are not statistically significant are omitted from the model. Variables shown in brackets are not available in the data.

Figure 1. Extension of the Blau-Duncan Model to Include Control of the Means of Production and Authority for Great Britain and the United States Separately; Men Only*

(Farkas, 1976:476) and provides a standard for assessing the explanatory power of the simpler models.

Other measures. Father's and respondent's education are measured in years of schooling. For father's and respondent's occupational status we use Duncan's (1961) SEI index which is essentially an average of income and education for each detailed census occupation.¹⁸ Personal income (available only in the 1974 and 1976 surveys) is job earnings, before taxes or other deductions, for the preceding

year in dollars.¹⁹ To correct for inflation between the two surveys, we converted income to 1975 dollars using the consumer price index (U.S. Bureau of the Census, 1976:433).

Class identification is the respondent's self-assignment to a choice of four classes: lower, working, middle, and upper (following Centers, 1949). Several sociopolitical attitudes also are analyzed. Respondents were asked whether they had

¹⁸ We used the coding procedure in Featherman et al. (1975).

¹⁹ Income was originally coded into twelve categories, ranging from under \$1,000 to \$25,000 or over, and we use the midpoint of each category to convert it into dollars (except for the highest open-ended category which we estimated at \$30,000).

"hardly any confidence at all," "only some confidence," or "a great deal of confidence" in the people running *organized labor*. *Political party identification* ranges in six categories from strong Republican to strong Democrat. *Vote in 1972* is whether the respondent voted for Nixon or McGovern in the 1972 presidential election. *Political attitude* (available only in 1974 and 1976) is self-placement on a seven-point scale of political views from extremely conservative to extremely liberal. Exact wording of the items is given in NORC (1976).

Statistical Methods

We estimate our models by ordinary least squares (OLS) regression methods. These assume that relations among variables are, to a reasonable approximation, linear and additive. There is good evidence that this is a reasonable assumption for variables used in the Blau-Duncan model (e.g., Duncan et al., 1972) and in general (e.g., Middleton, 1973). We will present evidence concerning nonlinearities and interactions involving control and authority and show that the linear approximation is fully adequate.

RESULTS

Description of the American Class Structure

By the Marxian definition, the class structure consists of a small upper class and a much larger lower class, with 11% of

the men being capitalists and 81% workers (see Table 2). By Dahrendorf's definition the upper class is larger and the lower class correspondingly smaller; 44% of the men are in the command class and 48% in the obey class. The remaining 8% are in the marginal group which Marx calls the *petite bourgeoisie* and Dahrendorf defines as classless. There are some interesting sex differences. Women are only half as likely as men to be in Marx's capitalist class, slightly more likely to be workers, and equally likely to be *petit bourgeois*. Women are also less likely than men to exercise authority in the workplace, particularly at higher levels. These sex differences could be due to direct discrimination (e.g., Thurow, 1975:178-9), or to differences in preferences or in socialization (e.g., Mednick et al., 1975), or to some combination of these and other factors; unfortunately our data do not speak to this question.

There is only a modest overlap between class position as defined by Marx and as defined by Dahrendorf, indicating that the two models are empirically as well as conceptually distinct. About one-quarter of Dahrendorf's command class are capitalists by Marx's definition, the remaining three-quarters being workers in Marx's scheme (see Table 2). Put differently, the correlation between control of the means of production and authority is a modest .4, noticeably lower than, for example, the .6 correlation between education and occupational status, the key variables in the Blau-Duncan model.

Table 2. Mean Duncan Socioeconomic Status Scores by Authority and Control of the Means of Production; Percentage of the Total Population in Each Cell Is Given in Parentheses (for U.S. Men and Women Separately; Full-Time Workers Only)

	Dahrendorf: Authority in the workplace							
	Men				Women

¹ This is the *petite bourgeoisie* in Marx's scheme and the classless group in Dahrendorf's.

² Excludes the *petite bourgeoisie* or classless group.

Class and the Blau-Duncan variables. Neither control of the means of production nor authority is closely related to occupational status. The mean occupational status of each cell in the cross-tabulation of authority and control, given in Table 2, shows little systematic variation. The correlation between occupational status and these alternative concepts of class is quite modest ($\text{Eta} = .3$ for men and $.2$ for women, a figure equal to the multiple correlation between occupational status on the one hand and Marx's and Dahrendorf's classes on the other, with all interactions and nonlinearities in Marx's and Dahrendorf's classifications taken into account). Moreover, neither control nor authority is much associated with education, the correlation being only $.1$ for both.

Class and Income

Controlling the means of production and exercising authority both substantially increase a man's income. Control alone explains 9% of the variance in income, and the continuous version of authority 14%, while both jointly account for 17% of the variance. By way of comparison, education alone explains 13%, occupational status 18%, and both together 20% of the variance in income. Since the Blau-Duncan model is well established in the empirical literature it is perhaps most appropriate, if only on the grounds of parsimony, to consider the amount of variance that the class variables add in addition to that explained by the Blau-Duncan variables. This is a conservative procedure since it assigns the joint variance to the Blau-Duncan variables, but that is not of much practical importance since the joint variance is not large. The basic Blau-Duncan variables explain just under 20% of the variance in men's income in these as in many other data sets (e.g., Duncan et al., 1972), a disquietingly low figure that has led to some perhaps premature speculation on the importance of luck (Jencks et al., 1972; Sahota, 1978:7-9). Simply adding Marx's control of the means of production to the Blau-Duncan variables explains an additional 5% of the

variance while adding authority in Dahrendorf's original dichotomous form is almost equally efficacious and adding our continuous authority measure is noticeably more so (Table 3, lines 2, 3 and 4). In fact, in a model with only our continuous version of authority and the Blau-Duncan variables, authority is the single most important determinant of income.²⁰ When authority and control are both added to the Blau-Duncan variables they increase the explained variance by 9%, almost half again the original figure (line 6), and authority's effect is second in magnitude only to occupational status (Panel C). In metric terms, men in the upper command class earn just under five thousand dollars more than those in the obey class and capitalists earn just under four thousand dollars more than workers (Panel D).

These results are robust under alternative specifications of the model. The same conclusions are reached when one considers the log of income, as is usual in economics, and when various other variables, including labor force experience, are added to the Blau-Duncan model.²¹ Mod-

²⁰ It has a standardized partial regression coefficient of .28 while occupational status, the next most important variable, has a path of .24.

²¹ The variance explained in log income is noticeably lower but the success of the various theories, relative to the baseline model or to each other, is much the same and they together increase the explained variance in men's income by nearly half. Following the nomenclature of Table 3, we have for log income:

Models	United States	
	Men	Women
1. Baseline: Blau-Duncan variables only. $R^2 =$	13.4	19.4
<i>Increases in R^2 by adding:</i>

Education	.184* ^d	.341*	.250*
Occupational status	.236*	.251*	.234*
<i>Panel D. Metric partial regression coefficients for model 6 (U.S.) or 5 (G.B.)</i>			
Marx: control of the means of production (1=capitalist)	\$3,967* ^d	-\$155	£1,265*
Dahrendorf: authority (1=upper command class in U.S.; command class in Britain) ⁴	\$4,816* ^d	\$1,148*	£446*

* Increment in R² over model 1 is statistically significant at p<.05 or partial regression coefficient significantly greater than zero at p<.02.

¹ Father's education is not available in Britain.

² Wright and Perrone's model necessarily explains the same variance as this model.

³ Dummy variables (eight for U.S., three for Britain) representing the cells in the cross-tabulation of authority and control. See text for details.

⁴ Continuous version in the U.S. In Britain only the dichotomous version is available.

^{a, b, c} The R² for the higher numbered model is significantly greater than that for the lower numbered model(s) at p<.05. The comparisons are: a-model 4 vs. 3; b-5 vs. 2 and 5 vs. 3; c-6 vs. 2 and 6 vs. 4.

^d Difference between men's and women's regression coefficients is significant at p<.05.

maximum possible variance in income, we have not confounded this comparison by introducing additional control variables. However, when we include the additional variables suggested by Treiman and Terrell (1975a), we find that both authority and control of the means of production remain significant determinants of men's income, increasing the variance explained by 5% from 37 to 42%:

Models

1. Baseline: Blau-Duncan variables plus siblings, hours worked per week, experience, experience squared, children under six, and children aged six to seventeen. R² =

United States
Men Women

36.8 31.3

Increases in R² by adding:

2. Marx: control of the means of production	2.4*	0.0
3. Dahrendorf: authority (dichotomous)	2.4*	0.0
4. Improved Dahrendorf: authority (continuous)	4.1*	0.2
5. Marx and Dahrendorf	3.5*	0.0
6. Marx and improved Dahrendorf	4.9*	0.2
7. Maximum: all interactions, etc.	5.3*	2.4

In our preferred Model 6, work experience (beta=.39 for experience and -.27 for experience squared) and education (.25) are the most important determinants with authority (.19) sharing third place with occupational status (.17), and control of the means of production (.10) coming next.

ifying Marx in a way analogous to our modification of Dahrendorf does not change the results; a trichotomous version of Marx's model which makes further distinctions between workers one level below the top of the hierarchy and those more than one level below the top explains no more of the variance in either men's or women's incomes. Moreover, virtually all of the influence of authority and control is captured by the postulated linear and additive effects. Adding all possible detail, interactions, and nonlinearities increases the explained variance by less than a third of 1%, an entirely insignificant figure (compare lines 6 and 7).

We conclude that our analysis of class and income is supported by the data for American men, with our improved version of Dahrendorf's authority being more important than either Dahrendorf's dichotomous authority model or Marx's control of the means of production.

Women's income. For women, quite unlike men, neither controlling the means of production nor exercising authority offers any clear monetary rewards. Exercising authority has an effect in the predicted direction but it is small (line 4). In metric terms, being at the top of the authority hierarchy is worth something over a thousand dollars in additional income for women, less than a quarter of the figure for men (Panel D). Belonging to Marx's capitalist class has no significant effect on a woman's income (line 2 and Panel C). In metric terms, women seem to lose just under two hundred dollars by being capitalists while men, in contrast, gain almost four thousand. The difference between the large rewards men receive from exercising authority and controlling the means of production and the small or nonexistent rewards which accrue to women is striking and statistically significant. These results are not in accord with the predictions of Marx or Dahrendorf, or with our analysis of the link between class and income.

Our findings have implications for previous analyses of sex differences in income. A variety of studies show that women earn less than men (e.g., Featherman and Hauser, 1976; Mincer and

Polachek, 1974; Treiman and Terrell, 1975a). Since women are less likely than men to be capitalists or to exercise authority in the workplace, it has been suggested that this may account for some of the male-female income difference (Fligstein and Wolf, 1978). Our data suggest that the fundamental problem is that women do not receive the pay men do even when they do obtain capitalist and supervisory positions. It is not simply the modest differences in the *distribution* of class positions, but the sharp differences in the *process* whereby these positions are converted into earnings that are responsible for some of the sex difference in earnings. Using the regression standardization procedure suggested by Duncan (1968a), we find that sex differences in the distribution of control of the means of production and authority account for only 2% of the gap between men's and women's average income while differences in the process of converting control and authority into earnings account for 14% of this gap. Taking both of these differences into account explains fully 25% of the gap between men's and women's earnings.²²

Our data allow a limited examination of the reasons for this. First, occupations which make up the upper classes in Marx's scheme are rather different for men and women in ways which suggest that the firms women control may be less profitable than those men control. The largest groups among male capitalists are managers and administrators (39%), farmers (8%), lawyers (6%), and insurance agents (6%), while the largest groups among women capitalists are managers

²² A predicted mean income for women standardized for sex differences in the distribution of control and authority was obtained by substituting the male means for these two variables into the female regression equation. A prediction controlling for differences of process was arrived at by substituting the male unstandardized regression coefficients (i.e., b's) associated with control and authority for the female coefficients in the same equation, and a prediction taking differences of both distribution and process into account was obtained by substituting both the male means and regression coefficients for control and authority in the female equation. For an analysis of the male-female income gap which takes into account control of the means of production, authority, and other variables see Roos (1978).

and administrators (20%), registered nurses (11%), restaurant, bar, and cafeteria managers (9%), clerical supervisors (6%), and cooks (6%). Moreover, women in Dahrendorf's command class may hold less important supervisory positions than do men. Among men, the largest groups comprising the command class are managers and administrators (19%) and foremen (6%), while among women the largest groups comprising this class are secretaries (11%), registered nurses (9%), managers and administrators (9%), and bookkeepers (5%). Furthermore, women are less likely than men to supervise at higher levels, as we have seen (Table 2). Finally, women capitalists appear to control smaller firms than men do. Only one out of six firms controlled by women have more than two levels of command while almost half of those controlled by men are this large.

REPLICATION AND EXTENSION: DATA FROM GREAT BRITAIN

We present here an analysis of data from Great Britain which serves three purposes. First, we show that the results we have presented for income (and will later present for class consciousness and politics) are not unique to the United States, a most unusual society in many ways, but appear in another advanced industrial society as well. Second, we compare the effects of class and status on income and class consciousness in the United States and Great Britain. Third, we present for Britain some evidence on the transmission from generation to generation of class position as defined by Marx and Dahrendorf.

Since Tocqueville wrote *Democracy in America* more than a century ago, observers on both sides of the Atlantic have seen American society as open and egalitarian in contrast to class-bound and inegalitarian Britain. Marx (1867a:449) refers to Britain as the "classic ground" of capitalism and based his abstract model of class largely on it (Giddens, 1973). In contrast, he sees the United States as lacking a strong consciousness of class since classes there "have not yet become fixed but continually change and interchange

their elements" (1852:444). Dahrendorf (1959:275) predicts that industrial class affiliations will generally have little consequence for political attitudes in industrial societies but makes an exception for Britain, where he expects a high correlation between class and politics. Recent research on stratification (Treiman and Terrell, 1975b), class consciousness and voting (Alford, 1963; Rose and Urwin, 1969), and subjective aspects of stratification (Bell and Robinson, 1978; Robinson and Bell, 1978) make similar points. In part because of these differences, research in the U.S. almost exclusively emphasizes continuous measures of status or prestige while British research tends to stress categorical class divisions (e.g., Blau and Duncan, 1967; Treiman and Terrell, 1975a in the U.S., and Goldthorpe and Llewellyn, 1977; Westergaard and Resler, 1975, in Britain).²³ By comparing status and class models we will be able to see whether this difference in emphasis is appropriate and what is lost by emphasis on one model to the exclusion of the other.

Data. The British data are from a representative national survey conducted by Butler and Stokes (1969) of the populations of England, Scotland, and Wales, aged 20 or over. We restrict our analysis to the 686 men in 1964 who were gainfully employed. We have not been able to analyze working women in Britain because the number of cases is very small and the data do not allow us to make the crucial distinction between full-time and part-time workers.

So far as possible we have defined variables in the British data so as to be comparable with those in the U.S. data but, where necessary, we have used measures which are appropriate to each country, so

²³ Obviously there are exceptions to these one-sided views, especially among the theoretical traditions in both countries but also in the quantitative traditions. Ironically, the class measures employed by British researchers may in fact reflect a status dimension. For example, the social class measure of the British Registrar General's Office, often employed by British sociologists, is only very slightly correlated with class in Marx's sense (.32) or in Dahrendorf's (.22) and far more resembles occupational status ($r = .79$) or prestige ($r = .66$).

as to do justice to the idiosyncracies of each stratification system.²⁴ Additional analyses using identical stratification measures in the two countries resulted in essentially the same substantive conclusions as those reported below.

Income

The British data clearly corroborate our results on income in the U.S. Control of the means of production has a strong effect on income, as large as that of education or occupational status, while authority has an appreciable and statistically significant, albeit smaller, effect (see the last column of Table 3).²⁵ Taken together, control and authority increase the variance explained by the traditional Blau-Duncan variables from 24 to 33%, an increase of nearly half. It is noteworthy that Marx's control, when it alone is added to the Blau-Duncan variables, is the single most important determinant of income

and when entered with authority is very nearly as important as education and occupational status (Panel C). Control of the means of production is more important than authority in Britain, although the comparison is problematic since the British data lack the continuous measure of authority which we have shown to be superior in the U.S. In all, the great importance of control of the means of production may indicate that, as Marx (1867a:449) assumes, Britain is more of a classical capitalist society than the U.S.

Family Background and Class Position

Having shown that acquiring control over the means of production and exercising authority in the workplace have important consequences for income inequality, we now look briefly at their causes, in particular the extent to which advantages are handed on from parent to child. The British results in Figure 1 suggest that there are two more or less distinct processes by which advantage is passed on from one generation to the next, one a *status* system centering on education and occupational status and the other a *class* system centering on control of the means of production and authority. Having a father who controls the means of production appreciably increases a son's chances of controlling them himself. Fathers probably hand over the family farm or business or provide investment capital. Having a father with high occupational status also confers a small but statistically significant advantage. Family background also tells in getting into the command class. Having a father in the command class makes no significant difference to a son's chance of getting into that class but it does help to have a father who controls the means of production or has high occupational status. In all, contrary to what Marx and many others have assumed, class position does not appear to depend much on family background. Only 2% of the variance in control and 1% in authority is explained by family background. In this sense, the class system is less rigid than the status system, in which family background explains 15% of the variance in education and almost 13% in occupational status.

²⁴ To take into account peculiarities of the British educational system, education is coded as in Treiman and Terrell (1975b:567-72, 580-1). Lacking a socioeconomic index for Britain, we coded son's (and father's) occupational status according to the son's weights from a canonical procedure using father's occupation (dummy-coded), education, and income as the criteria (for details see Kelley et al., 1977). The same substantive conclusions as those discussed in text were arrived at using Treiman's (1977) standard international prestige scores (Robinson, 1978). Control of the means of production and authority are operationalized in a manner identical to our classification in the U.S. except that only a dichotomous version of authority is available. Personal income ranges in thirteen categories from less than £250 to over £1,950 and we converted this metric to pounds using the midpoint of categories (except for the highest open-ended category which was estimated at £2,852). The attitudinal variables are similar to those available in the U.S. data. Class identification is self-assignment to a choice of the middle or working class. For political party identification and vote in 1964 (the most recent election), Labour supporters are scored one, Liberals two, and Conservatives three. Political attitudes are measured by self-placement on a three-point left/right continuum. Details are available on request.

²⁵ Control of the means of production and the dichotomous measure of authority jointly explain 14% of the variance in men's income compared with 24% for the Blau-Duncan variables. Judging from the U.S. results, if a continuous version of authority were available, the variance explained by the class variables would probably be even closer to that explained by the Blau-Duncan variables.

The difference is not so much in the *direct* effects of father's status and control of the means of production, both probably having largely to do with wealth and property (Kelley, 1978), but in the *indirect* effects via education. (Father's occupational status has a substantial effect on his son's education and so indirectly on his son's occupational status; fathers with high status jobs manage to get their sons more education and that in turn allows the sons to get high status jobs.) But father's control of the means of production has only a small effect on education and father's authority has virtually none. At the same time son's education has no appreciable effect on his control or authority, so there are no indirect effects in the British class system.

Our U.S. data do not include measures of father's control or authority, but as far as we can tell from the data that are available, the American situation is not dissimilar to the British. Coming from a family with high occupational status confers a modest direct advantage in gaining access to privileged positions in Marx's sense. Furthermore, coming from a family with high educational or high occupational status confers a modest indirect advantage since it leads to more education which, in the U.S., helps in gaining control of the means of production and especially in gaining positions of authority. But in all, coming from a high status family, in the U.S. as in Britain, confers only a modest advantage in control or authority. How-

ever, judging from the British data, it is not unlikely that coming from a family that controls the means of production confers a more substantial advantage. A more detailed cross-national analysis is presented elsewhere (Robinson, 1978; see also Kelley, 1978).

Class Consciousness and Politics

The limitations of our data and the imprecision of some of Marx's and Dahrendorf's conceptions preclude a complete test of their theories of class consciousness and politics. Nevertheless, we can perform limited but useful tests of, first, the extent to which objective class position leads to a sense of awareness of belonging to a particular class; second, the extent to which it leads to a subjective perception of having interests which are different from (and possibly in conflict with) those of other classes; and third, the effect it has on political attitudes and behavior.

Class identification. Education, occupation, and income long have been recognized as important determinants of class identification (Centers, 1949), and more recent research in both the U.S. and Britain confirms their importance (e.g., Hodge and Treiman, 1968; Runciman, 1966). None of these studies, however, has examined the effect of objective class position in either Marx's or Dahrendorf's sense. We present the results of such an analysis in Table 4.

Table 4. Effects of Control and Authority¹ on Class Identification and Political Attitudes (Increments in the Proportion of Variance Explained [R^2] over That Explained by the Blau-Duncan Model;² Separately for British Men and U.S. Men and Women)

Dependent Variable	British Men			U.S. Men			U.S. Women

Political party	2.1*	1.6*	2.5*	0.4*	0.1	0.4	1.8*	0.4	1.8*
Vote	2.4*	2.1*	3.1*	0.0	0.1	0.2	1.0*	0.4	1.1*
Political attitudes	0.3	1.6*	1.6*	0.4	0.4	0.6	0.1	0.0	0.1

* Increment in R^2 over the Blau-Duncan model is statistically significant at $p < .05$.

¹ Continuous version in the U.S. In Britain only the dichotomous version is available.

² Includes father's education and occupational status, respondent's education and occupational status in the U.S.; father's education is unavailable in Britain.

Among British men, the importance of both Marx's and Dahrendorf's class concepts is reasonably clear, although they are somewhat less important than occupational status (not shown in the Table to conserve space). Both capitalists and command class members are more likely to identify with the middle class, as predicted (Table 4, row 1). Somewhat under a third of the effects of both control and authority are indirect through income. This finding is consistent with Marx (1867b:708-9; Marx and Engels, 1848:22ff), who argues that disparities in wealth (together with other factors) lead to the development of revolutionary consciousness among workers, and with Dahrendorf (1959:216-7, 242), who argues that latent interests are more likely to become manifest when authority classes are superimposed on economic inequalities. Control of the means of production is more important in Britain than in the U.S., indicating here, as for income inequality, the greater salience of the class structure in Britain.

Among American men, both Marx's and Dahrendorf's class models are significant determinants of class identification, although their effects are small relative to the sizeable effect of occupational status (not shown in the Table to conserve space), indicating that Americans are more attuned to status than to class distinctions. Consistent with both Marx and Dahrendorf, about half of the effect of both class variables is indirect through income. However, contrary to prediction, among U.S. women neither control nor authority has any effect on subjective class identification. This may be in part because there is no indirect effect through income, since women do not earn much more when they get into the capitalist or command classes, or because they stress their husband's characteristics more than their own (e.g., Ritter and Hargens, 1975; Rossi et al., 1974:178).

For class identification and the political variables we will consider below, unlike income, our continuous version of authority was no better than Dahrendorf's dichotomous version, although it was no worse (indeed, the results are so close that we have shown only the continuous ver-

sion in Table 4). On the whole it appears that our modification of Dahrendorf gives a quite plausible account of the link between class and income but offers little new insight into the effects that objective class position has on class consciousness and class conflict.

Political attitudes and affiliations. Marx's (1871:388; Marx and Engels, 1848:24; 1885:106-17) arguments that "every class struggle is a political struggle" and that progressive political parties are the advance troops of the revolution have been so influential that it frequently has been assumed that the political struggle is mainly a struggle between classes (e.g., Alford, 1963:38; Lipset, 1960:234). There is, however, hardly any evidence on Marx's theory since virtually no empirical studies use class in his sense, although numerous studies have employed a manual/nonmanual dichotomy, or prestige, or status (Knoke, 1976:62). In contrast to Marx, Dahrendorf (1959:272-6) argues that in "post capitalist society" there has developed an "institutionalization of industry" and an "isolation of industrial conflict" from political conflict with the result that "the participants of industry, upon leaving the factory gate, . . . leave behind their industrial class interests. . . ." He concludes that in most modern societies industrial class membership will have no effect on political attitudes or behavior. However, he does make an exception for Britain, where he expects a fairly high correlation between class and politics because of the high politicization of the labor movement there.

In Britain, consistent with Marx's and Dahrendorf's expectations, class has an appreciable influence on politics (see Table 4). British capitalists are significantly more likely than workers to identify with the Conservative party and to have voted Conservative in the most recent election, although they are no more apt to claim to have conservative political attitudes. Command class members are significantly more likely than obey class members to identify with the Conservative party, to have voted Conservative, and to view themselves as politically to the right. Virtually none of these class effects is attributable to the fact that

capitalists or command class members have higher incomes.

Leaving aside the special British case, Marx and Dahrendorf have conflicting expectations as to the politicizing effects of class position and our U.S. data support both theorists. This is, of course, only possible because their conceptions of class differ. Whereas authority in the workplace has virtually no politicizing effect for either men or women, control of the means of production influences the political stances of both sexes. American capitalists are slightly but significantly more likely to lack confidence in labor leaders and to oppose the Democratic party, the presumed vehicle of their opponents' interests in a Marxian class struggle. These differences are particularly marked among women, for whom control of the means of production is second only to father's education as a predictor of party identification. Women capitalists are also significantly more likely than women workers to have voted Republican in the 1972 presidential election, although class position made no difference in the electoral choice of men or in the perceived liberalism of either men or women. Few, if any, of these political differences come about because capitalists earn more than workers.

Our analysis of the class bases of class consciousness and politics is necessarily preliminary and suggestive, based as it is upon attitudinal measures which are not fully adequate to the task of measuring Marx's and Dahrendorf's theoretical constructs (see, for example, Hazelrigg, 1973) and are subject to substantial random measurement error. The small increments in variance explained may reflect the inadequacy of the measures employed. The conventional Blau-Duncan status variables do not explain much variance in politics either—only about 6% on average, compared with over 20% in income. Thus the modest increments from adding class variables represent a sizable improvement in prediction. In sum, our analysis is suggestive of a significant but far from dramatic link between class and politics, but we must await the development of better measures for the final word on this.

CONCLUSION

Our analysis suggests that the United States and Great Britain have not one but two distinct stratification systems. Each consists of two separate components. Marx's control of the means of production and Dahrendorf's exercise of authority in the workplace are the central features of the class system which stems from the hierarchical organization of work; education and occupational status are at the core of the status system which is the focus of the Blau-Duncan paradigm. Class and status analyses are based on different theoretical premises, and the two stratification systems are only loosely related, with advantage being passed on from one generation to the next mainly within rather than between them. Both components of each system have important consequences, primarily for income and secondarily for class identification and politics.

In the United States and Great Britain, both control of the means of production and authority have large and statistically significant independent effects on men's income, increasing by half again the variance explained by status variables. The income of American women, in contrast, is little influenced by class, a difference which explains a substantial part of the male-female income gap.

The authority component of the class system is, we suggest, best viewed not as a simple dichotomy, as Dahrendorf would have it, but as a continuum. Because they have more power to set salaries, greater responsibility, and higher marginal productivity, first line supervisors will earn more than the ordinary workers who are subordinate to them. But for the same reasons, those who supervise first line supervisors will, in turn, earn more than *their* subordinates, and so on. Each level of the authority hierarchy will thus, we argue, earn more than the levels below it. The data for American men support our claim. Our continuous version of authority explains significantly more variance in income than Dahrendorf's dichotomy, indicating that there are important income differences within the command class.

The effects of the two class variables on class identification and politics are all in the predicted direction and most are statistically significant, although small. The American public appears to exhibit a limited form of class consciousness, with control of the means of production creating some political differences. As both Marx and Dahrendorf predict, class is more salient for British men, with those who control the means of production or exercise authority in the workplace being more likely to identify with the middle class and to support the Conservative party.

There are two major traditions of research on stratification. The class tradition, based originally on Marx's work and extended by Dahrendorf, focuses on control of the physical means of production and authority over the labor of others, and emphasizes the conflict and inequality that inevitably results from the hierarchical organization of work. The status tradition, which led ultimately to the Blau-Duncan paradigm, stresses open and competitive acquisition of educational skills and occupational status. Researchers working within each tradition have generally ignored the other; many British researchers, for example, emphasize class while most American research focuses on status. The two systems described by these traditions are loosely related, but they are by no means identical, and neither can be safely ignored. Position in one system is only modestly correlated with position in the other and empirically each has significant effects, independent of the other, on income, class consciousness, and politics in both the United States and Great Britain. A one-sided approach focusing exclusively on either system, thus, seems both unwise and unnecessary. For this reason we have taken this first step toward a merger of the class status traditions.

OVERCROWDING IN THE HOME: AN EMPIRICAL INVESTIGATION OF ITS POSSIBLE PATHOLOGICAL CONSEQUENCES*

WALTER R. GOVE
Vanderbilt University

MICHAEL HUGHES
Vanderbilt University

OMER R. GALLE
University of Texas

American Sociological Review 1979, Vol. 44 (February):59-80

Several recent studies have suggested that, contrary to investigators' initial expectations, household crowding typically has little impact on humans. Using a sample collected in Chicago which minimized the collinearity between crowding and socioeconomic variables, we find that both objective crowding (as measured by persons per room) and subjective crowding (as indicated by (1) excessive social demands and (2) a lack of privacy) are strongly related to poor mental health, poor social relationships in the home and poor child care; and are less strongly, but significantly related to poor physical health, and to poor social relationships outside the home. Furthermore, these three crowding variables taken together, on the average, uniquely explain as much (and with many indicators, more) variance in our dependent variables as is uniquely explained by the combined effects of sex, race, education, income, age, and marital status. It is suggested that attention be turned away from the question of whether crowding ever has effects to the study of factors which maximize or minimize its effects.

As Baldassare (1978) has demonstrated, a large number of factors in the sixties and early seventies led to the belief by a substantial part of the scientific community and most of the general population that high levels of density have serious detrimental effects on humans. During this time there were a number of studies on the effects of high levels of density on human behavior. From these studies it became obvious that it was necessary to distinguish between density at the level of the macroenvironment (as measured, for example, by persons per acre) and overcrowding in the macroenvironment, such as crowding in the home (e.g., Carnahan et al., 1974; Galle and Gove, 1978). It is now fairly clear that while density at the macrolevel probably has some minor "pathological" effects, it is not a variable of major substantive importance (e.g.,

Galle and Gove, 1978). In contrast, the evidence on overcrowding in the home is much less consistent. It might be noted that overcrowding in the home is much more analogous to the overcrowding described in the numerous animal studies (Galle et al., 1972; Galle and Gove, 1978). More important is that relationships in the home are enduring and play a very important role in determining the well-being and behavior of the individual (e.g., Stokels, 1976; Baldassare, 1978). Disruption of these relationships due to overcrowding is thus apt to have serious consequences.

Virtually all the investigators who have reviewed the literature of the effects of overcrowding in the home have concluded that it suffers from a number of serious methodological problems and limitations. In spite of these limitations, the recent reviews of the literature by Fischer et al. (1975) and Chadwick (1972) conclude that density and crowding have at the very most extremely modest effects. Freedman (1975:7) takes an even stronger stand. He concludes that

high density (crowding) does not have generally negative effects on humans. Overall, with other factors equated, living, working,

* Address all communications to: Walter R. Gove; Department of Sociology; Vanderbilt University; Nashville, TN 37235.

This research was supported by NICHD Grant #5-RO1-HD-6911-02. We would like to thank Mark Baldassare, Claude Fisher, Lisa Heinrich, Tom Gregor, Nina Gove and William Rushing for their comments on an earlier draft.

or spending time for any reason under conditions of high density [and crowding] does not harm people. It does not produce any kind of physical, mental or social pathology. People who experience high density are just as happy and productive as those who experience lower density.

In contrast, we perceive the evidence as tentative but as suggesting that overcrowding, at least under certain conditions, does have detrimental effects (Galle and Gove, 1978). A generally similar position is taken by Altman (1975) and Baldassare (1978).

The best evidence on the effects of overcrowding in the home comes, of course, from data on individuals, but the vast majority of studies have used aggregate data (Galle and Gove, 1978). Some of the early studies on individuals suggest that crowding does have detrimental effects (Reimer, 1945; Chombart de Louwe, 1975; Schorr, 1966; Wilner et al., 1962). More recently there have been four studies using survey data looking at the effects of overcrowding in the home. The studies by Mitchell (1971) and Marsella et al. (1970) studied Asians and, as culture plays a major role in determining the effects of crowding (see below), it is probably inappropriate to draw direct inferences from these studies regarding the effect of crowding in western culture. Both of these studies suggested crowding had clear but not overwhelming effects; however, the study by Marsella et al. (1970) is so flawed by its small sample size and lack of controls that it should be viewed with great caution. Baldassare (1978) has recently conducted a secondary analysis of survey data collected for purposes other than looking at the effects of crowding. He has, in our view, good measures of interpersonal relationships and poor measures of mental health. He found that overcrowding was related to poor interpersonal relationships in the home but not to poor mental health. Recently Booth and his associates conducted a major survey in Toronto specifically to look at the effects of overcrowding. These results are available in a series of papers (Booth and Cowell, 1976; Welch and Booth, 1975; Booth and Edwards, 1976; Welch, 1975; Booth and Johnson, 1975; Booth, 1975; Johnson

and Booth, 1975; Edwards and Booth, 1975) and a book (Booth, 1976). Booth (1976:1) concludes that "perhaps the most important finding of this study, contrary to our expectation before we began the study, is that crowded conditions seldom have any consequences and even when they do their effects are very modest." Unfortunately, as is demonstrated in detail elsewhere (Gove and Hughes, 1979b), Booth's sample is so atypical and homogeneous and the measurement and analysis are so flawed that it is difficult to draw any conclusions about the effect of crowding from the Toronto study.

In conclusion, it is widely believed by persons outside the scientific community that overcrowding is an important variable. In contrast, most of the recent investigators of the effects of crowding on humans do not see it as a variable of major importance. However, a careful reading of the literature indicates that the evidence is inconclusive.

CONCEPTUALIZATION OF CROWDING

The theoretical literature on the experience of crowding focuses on two analytically distinct but interrelated concepts: an excess of stimulation and a lack of privacy. For example, Desor (1972) defines crowding as "receiving excess of stimulation from social sources." Other investigators who have emphasized stimulus overload in the experience of crowding are Rapoport (1972), Galle et al. (1972), Wohlwill (1974), and Milgram (1970). Perhaps the best theoretical discussion of the effects of the environment on behavior is the book by Altman (1975). Altman, while recognizing the importance of stimulus overload, feels that the concept of privacy is the key to understanding crowding. We would note that although there is an extensive *conceptual* literature on privacy (e.g., Altman, 1975; 1976), and stimulus overload, there has been no effort to measure these variables in the study of crowding in the home. In combination, these concepts suggest that the experience of crowding involves an excess of social stimuli, generally in the form of demands on one, combined with an inability to regulate or control when one

receives the demands and how and when one is expected to respond to them.

A key factor in understanding the effects of crowding is the recognition that culture determines what are appropriate demands and appropriate responses. Furthermore, it appears that in all cultures there are ways in which one can socially construct a situation and setting where one can withdraw from interaction and experience privacy, and there are very sharp cultural variations in how social interaction and privacy are regulated (Hall, 1966; Anderson, 1972; Gregor, 1977; Morgan, 1881; Mitchell, 1975; and Altman, 1975).

Virtually all the work on the determinants of behavior posit an optimal level of social stimuli which is associated with effective behavior and treat an excess or surfeit of stimuli as producing problematic behavior. This is true of work on isolation and crowding on animals (Allee, 1938; Galle and Gove, 1978), isolation and crowding in humans (Altman, 1975; Levi and Anderson, 1975; Galle and Gove, 1978; Gove et al., 1978), system analysis and cybernetics (Manderscheid, 1975), and stress theory (e.g., Welford, 1974). If this model which has been developed independently from a variety of sources is essentially correct, then it seems plausible that the norms within a given culture would regulate social interaction so that persons in typical situations would experience an optimal level of social interaction. If this is the case then it would follow that in many societies, particularly a society as complex and diverse as ours, some persons, particularly those in certain atypical situations, would experience an excess of social demands and a lack of privacy. In summary, due to cultural differences in the normative regulation of interaction and privacy, it seems likely that crowding would be experienced in most cultures by those persons who experience the most demands and have the least privacy.

If this analysis is correct, then some persons in our society should experience crowding despite the fact that, compared with other societies, our levels of crowding are low. Most investigators appear to assume that the greater the number of per-

sons per household, the greater the number of role obligations and experienced demands and hence the greater the experience of crowding. Also, implicit is the assumption that if the number of persons is held constant, when there are comparatively few rooms individuals will be less able to regulate their interaction, and hence will have less privacy and experience more crowding.

The notion that demands and lack of privacy are produced by the excess of persons per room and not simply by the number of persons is based on several assumptions. First, crowding results from a situation characterized by the inevitability of contact between persons, and an inability for persons to control the presence of others. Second, close proximity of persons increases the likelihood of attempted interaction. Third, a high ratio of persons to rooms will increase the degree one is obligated to be responsive to others. Fourth, in a crowded household, since everyone's daily activities may be easily observed by others, the most intimate aspects of one's 'self' are exposed and one lacks the back regions which Goffman's (1959) analysis suggest are important for both the maintenance of 'self' and for the effective performance of one's activities.

These assumptions seem reasonable and have resulted in the almost ubiquitous use of the measure produced by dividing the number of persons by the number of rooms. These assumptions, however, are untested. Furthermore, it seems obvious that the experience of crowding may involve other factors. Baldassare (1978) has suggested that the key variable is power and that individuals with power will regulate their environment so that they do not experience crowding. Although power is obviously relevant, we believe that socially defined role obligations are probably more important. Thus, a wife and mother has role obligations towards her husband and child which may result in an excess of experienced demands and a lack of felt privacy (e.g., Gove and Geerken, 1977; Gove and Hughes, 1979a). In situations where two different intimate role relationships come into play (as, for example, when one's mother-in-law is staying in one's house), there is apt to be a break-

down in the normative regulation of interaction which results in an excess of (often conflicting) demands and intrusions into intimate interactions. In other cases some persons or some families, for a variety of reasons, including intellectual and/or social incompetence, simply may function in a fashion which produces high levels of experienced crowding (e.g., Booth, 1976). In fact, in our society the role of child appears to be institutionalized as one where the norms regulating interaction are largely waived, and young children are allowed to make numerous demands and to intrude upon the privacy of others (e.g., see Aries's [1962] historical discussion of the "discovery" of childhood).

In summary, crowding has typically been operationalized by the measure persons/room (P/R) and conceptualized as the experience of an excess of social demands and/or a lack of privacy. However, there is almost no empirical evidence which validates that the number of persons per room is a good objective measure of crowding, and none of the studies of the effects of crowding in the home have looked at the experience of an excess of demands or a lack of privacy. The general model is that the subjective experience of crowding, as measured by an excess of demands and lack of privacy, acts as an intervening variable between an objective measure of crowding (P/R) and a set of dependent variables comprised of a number of moderate "pathological" states and behaviors. This model is presented in Figure 1. This model indicates that, in general, controlling for the subjective experience of crowding would greatly reduce the relationship between P/R and the dependent variables. However, from the above discussion this is clearly an oversimplification and there are a number of

variables other than P/R which relate to crowding. These include the household composition, the characteristics of the particular situation and the characteristics of the individual. Furthermore, there will be instances where the effects of crowding involve primarily special arrangements reflecting whether or not specific areas are designated for specific activities.

THE PRESENT STUDY

The present paper introduces two innovations which will help clarify whether or not crowding does have a (pathologic) effect. Given that there is a strong relationship between the social structure and crowding one would anticipate difficulty in identifying an independent effect of crowding due to problems of collinearity (Galle and Gove, 1978; 1979). We therefore have sampled in a manner so as to minimize the relationship between the social structure and crowding. Second, we begin by looking at a set of items that were specifically designed to measure immediate reactions to an overcrowded environment. Many of these items may be seen as reflecting the subjective experience of overcrowding. Not only will this be of assistance in studying the effects of objective levels of crowding but to psychologically inclined investigators it is the subjective and not the objective experience of crowding that is the key variable (e.g., Stokols, 1972a; 1972b; Altman, 1975).

The study was conducted in Chicago. Approximately 25 interviews were gathered from each of 80 selected census tracts within the city limits. To minimize the collinearity between socioeconomic status, race and crowding, we chose equal numbers of tracts from each of four different categories: (a) tracts with low levels of socioeconomic status and low levels

Figure 1. The General Model of the Effects of Crowding

crowding, (b) tracts with low levels of socioeconomic status and high levels of crowding, (c) tracts with high socioeconomic status and low crowding, and (d) high socioeconomic tracts which also had high levels of crowding. We also divided the sample by race. That is, we selected five predominantly black (more than 90%) tracts, five racially mixed tracts (10 to 90% black) and ten predominantly white tracts for each combination of crowding and socioeconomic status. The correlations between income and crowding were: (1) white, $r = -.130$, $p < .001$; (b) black, $r = -.064$, $p > .05$; (c) all respondents, $r = -.151$, $p < .001$. The correlations between education and crowding were: (a) white, $r = .159$, $p < .001$; (b) black, $r = -.078$, $p < .05$; (c) all respondents, $r = -.151$, $p < .001$. The correlations, although statistically significant, are not large, and it is clear that the collinearity between social class and crowding does not pose a serious problem with these data.

Households were chosen randomly from each census tract, and a randomly selected adult was interviewed in each of the selected households. The average interview lasted an hour and fifteen minutes. Besides the initial contact attempt, if no one was home there were three more contact attempts. The respondent was paid three dollars for completing the interview. We had a 68.1% response rate at the time of the screening interview and

a 89.1% response rate for the full interview. Although by historical standards this is a relatively high nonresponse rate, survey data is becoming increasingly difficult to collect, and we would note that these rates are similar to those of the only other recent survey done in Chicago (Ilfeld, 1976) and much lower than in the overcrowding survey done in Toronto by Booth (1976).

As Table 1 shows, the levels of crowding in our full sample are very similar to those of the nation as a whole, central cities in 1970 and Chicago in 1970, and discernibly less than those of the nation as a whole and central cities in 1950. As a consequence, if we find crowding does have an effect, this result is clearly relevant to understanding the effects of crowding in the general population. The second part of Table 1 compares the demographic characteristics of the sample with the population of Chicago in 1970. Although our sample was not drawn in a manner such that there was any reason to assume it to be representative of Chicago, our sample is in fact quite similar to the population of Chicago in terms of race, income, education and age. Furthermore, a separate analysis of blacks and whites indicates that these two subgroups of the sample correspond fairly closely to their counterparts in the Chicago population on a variety of demographic characteristics. In short, these data suggest that our sam-

^a Data taken from Carnahan et al. (1974) and 1970 census.

ple is relatively typical and does not involve a particularly unusual population. Unfortunately, there is a significant overrepresentation of females. This overrepresentation of females was also a characteristic of the only other recent survey in Chicago (Ilfeld, 1976) and the only other survey on overcrowding done in North America (Booth, 1976), and a review of other household surveys shows that it is a general characteristic of such surveys. As we control for sex in our analysis the overrepresentation of females should not pose a serious problem in determining whether or not overcrowding has significant effects.

Although we interviewed 2,035 respondents, 453 or 22% were living alone. As we were initially screening by households and the proportion of households in Chicago where persons were living alone in 1970 was 24%, this proportion is reasonable. Since our definition of crowding implies the presence of others, we have excluded persons living alone from our analysis. An analysis of the data which includes those who live alone shows that by excluding these persons from our analysis, we are weighting the analysis against the overcrowding hypothesis.

In our presentation we will rely exclusively on multiple regression analysis. The following characteristics of the respondent will be used as controls: (a) sex (0 = male, 1 = female); (b) race (0 = nonwhite, 1 = white); (c) marital status (0 = unmarried, 1 = married); (d) education (coded as actual years of education); (e) age (coded as actual years of age); and (f) family income (coded in 21 categories of \$2,000 intervals ranging from \$0 to \$40,000+). These are the traditional demographic variables considered by social scientists, and the literature suggests that they typically would be related to the dependent variables under consideration. Although technically the respondents are representative only of the census tracts sampled, we can think of no reason why the *effects* of income, education, sex, race, age and marital status should deviate markedly from those found in a more typically drawn sample. Thus, from the analysis, we should be able (1) to discover whether or not crowding does have an independent

effect on the dependent variables and, (2) by comparing this effect (if any) with that of the control variables, to get a fairly accurate idea of the effect of overcrowding relative to the effects of the variables traditionally considered.

Because of the technical requirements of multiple regression it is conceivable that its use could produce misleading results. For example, we had to dichotomize race and marital status, thereby losing information on some control variables. Similarly, with a variable such as age, it is conceivable that the relationship to some of the dependent variables might not even be monotonic. Furthermore, some of our dependent variables are not scales but dichotomized or trichotomized response categories to a particular question and these responses are sometimes highly skewed. We therefore performed a detailed set of dummy regression analyses to be sure that the results as presented reflect the actual relationships. In these dummy regression analyses, in addition to the other control variables we used four categories for marital status, four categories for ethnic status, and ten indicators of the occupational status of the household head. This very cumbersome analysis produced results virtually interchangeable with those presented and confirmed that (1) the relationship between our measure of crowding and the dependent variables is linear, (2) the use of dichotomized and trichotomized dependent variables distorts neither the pattern nor the strength of relationships, and (3) the way we categorized the control variables does not have a discernible impact on their effect.

The Experience of and Direct Reaction to Crowding

There has been very little effort to measure one's reaction to an overcrowded environment with survey techniques (e.g., Altman, 1975). Thus, for our questionnaire we picked 28 items that, on intuitive grounds, we felt would capture the persons' subjective experience of crowding and their ways of reacting to it. At the time we were developing items we were totally unaware of the literature, which

suggests that crowding is experienced by an excessive social demand and a lack of privacy. To group the 28 items into sets of interpretable clusters, we performed a number of factor analyses. Both orthogonal (with varimax and equimax rotations used) and oblique solutions were obtained. In every case the same six clusters were indicated.

From our analysis the two most prominent clusters to emerge were a set of six items that measured an overload of disruptive social demands and three items that measured the respondent's lack of privacy. The three items in the latter cluster were: "(1) In general, do you have as much privacy as you want? (2) At home do you have a place you consider to be your own? And (3) At home does it seem as if you can never be by yourself?" These items were added together to create a *lack of privacy* scale. Two of the items in the social demands cluster could be interpreted as partially reflecting the respondent's poor psychological state, and they were thus dropped from the remaining analysis to avoid biasing the results toward finding "pathological" relationships with crowding.¹ The remaining four items were added together to create a *felt demands* scale. The items in this scale were: "(1) Does it seem as if others are always making demands on you? (2) At home does it seem as if you almost never have any peace and quiet? (3) At home does it seem as if you are always having to do something for someone else? And (4) When you try to do something are you almost always interrupted?"

An analysis of the relationship of lack of privacy to the six control variables and P/R showed that P/R was much more strongly related than any of the control variables. P/R had a Beta of .330 ($p < .001$) while the next strongest Beta was .151 ($p < .001$) which was associated with race. (Whites experience less privacy than blacks, which may be interpreted as indicating that blacks, who have historically experienced more crowding, have developed norms which increase the amount of

privacy one can have under objectively crowded conditions.) In all, P/R and the six control variables explain 14.3% of the variance in the lack of privacy scale. Of the total explained variance 60.8% is uniquely explained by P/R, 21.7% is uniquely explained by the six control variables and 17.5% of the variance is collinear. A similar analysis with the felt demands scale also showed that P/R was more strongly related to it than any of the control variables. P/R had a Beta of .297 ($p < .001$) while the next strongest Beta was .143 ($p < .001$), which was associated with sex. (Women report more demands and interruptions than men, which may be interpreted as indicating that women experience an excess of demands due to their role obligations.) In all, P/R and the six control variables explain 15.5% of the variance in the felt demands scale. Of the total explained variance 46.5% is uniquely explained by P/R, 23.3% is uniquely explained by the six control variables and 17.5% of the variance is collinear. Thus as the theoretical literature predicts, our analysis indicates that lack of privacy and felt demands are strongly related to objective crowding (P/R) and that our two scales are good measures of the experience of crowding.

The other four clusters reflect the respondents' reaction to crowding. We used these clusters to create four additional scales. Two of the scales measure different types of withdrawal. The *physical withdrawal* scale is a two-item scale which measures the extent the respondent "desires" to leave the home "to get away from it all" and the extent he or she "actually" does so. The *psychological withdrawal* scale reflects the extent the respondent withdraws into a subjective world and ignores the demands of the immediate environment.² The relationship of P/R to both of these two scales is as strong as the combined relationship of the six

¹ The two items dropped were: "(1) When you are at home do others often get on your nerves, and (2) do you find it easy to relax at home?"

² The actual items were: (1) "Do you often ignore the demands of others? (2) Do you sometimes pretend to be busy even though you are not? (3) At home, when someone asks you to do something, do you sometimes agree to do it even though you don't think you will do it? (4) At home when others are talking to you do you sometimes pretend that you don't hear them?"

control variables. The third scale, labelled *lack of planning*, measures the lack of a short-run future orientation in the respondent, with specific reference to the disposition or ability to make plans.³ P/R is also as strongly related to this scale as the six control variables combined. The last scale, labelled *washed-out*, measures the extent to which the respondent cannot relate and respond to the requirements the day-to-day situation presents.⁴ Although P/R was not more strongly related to the washed-out scale than every control variable (sex was more strongly related), the relationship with P/R was strong and highly significant ($p < .001$).

In summary, these data indicate persons largely experience crowding in terms of excessive demands and lack of privacy. They react to crowding, as measured by P/R, with physical and psychological withdrawal. Furthermore, objective crowding apparently produces ineffectual planning behavior and a state of being physically and emotionally drained. Even if no other effects of crowding are found, it seems clear that crowding has important effects on the individual.

Mental health. We assume that the most direct impact of overcrowding is on the psychological state of the individual and that this impact in turn affects the individual's behavior. Thus, if crowding has adverse effects it would almost have to be related to poor mental health among persons who experience crowding. There is little direct support in the literature for the assumption that overcrowding is related to poor mental health; not only is there surprisingly little data on this relationship, but the available data suffer from serious measurement and other methodological problems⁵ (Galle and Gove,

1978). We devoted considerable effort in developing measures that would tap empirically and analytically distinct components of mental health and be valid and reliable. The detailed analysis presented in Brocki and Gove (1978) indicates that we were successful in this endeavor. A key component of poor mental health is the experience of psychiatric symptoms, which was measured by the *psychiatric symptom* scale presented in Gove and Geerken (1977). Another indicator of poor mental health is the absence of *positive affect*, with our indicator being items developed by Bradburn (1969). The early research by Bradburn and the subsequent research by others (Cherlin and Reeder, 1975) demonstrate that feelings of positive affect are largely unrelated to feelings of negative affect and that a combination of these two measures produces a better overall measure of mental health than either considered separately. As occurred with Bradburn's data, our scale of psychiatric symptoms is essentially uncorrelated with the scale of positive affect ($r = -.05$). We therefore z-scored the two scales and combined them to get a *mental health balance scale*. These measures treat mental health as involving a continuum. In an effort to identify something approximating a psychiatric case the respondents were asked, "Have you ever felt that you were going to have, or were close to having a nervous breakdown?" The measure *nervous breakdown* involves respondents who said yes to the first question and then indicated this had occurred in the past year. One of the themes in the literature is that overcrowding should be associated with a high degree of irritability. We therefore used the measure of *manifest irritation* presented in Gove (1978). Another theme in the literature is that crowding should be related to a sense of powerlessness, normlessness and belonginglessness. We combined measures of these feelings into a general *alienation* scale.⁶

³ The actual items were: (1) "Do you almost always plan your daily activities ahead of time? (2) Do you usually do what you plan to do? (3) Would you say you almost never make plans?"

⁴ The actual items were: "(1) Is there often so much going on about you that you can't think straight? (2) Do you often feel run down? (3) Do you often feel that it is impossible to finish anything? (4) Do you almost never seem to be able to do what you want to do? (5) Do you often feel lonely? (6) Do you almost always feel tired?"

⁵ A more detailed presentation of the problems and limitations of the existing data on the relation-

ship between overcrowding and poor mental health is available on request.

⁶ The respondents were asked if they agreed or disagreed with the following items: (1) The average person can have an influence on governmental decisions; (2) the trouble with the world today is that most people don't really believe in anything; (3) most

Furthermore, from the literature it seemed that overcrowding would be related to a poor self-evaluation, and thus we used the measure of *self-esteem* presented in Gove (1978). The final index was the respondents' happiness as measured by the general happiness question used by Bradburn (1969) and others.

Before we turn to the main analysis, a prior issue needs to be looked at. As noted, P/R almost invariably has been used as the objective measure of crowding. This use is based on the assumption that, with the number of rooms controlled for, the number of persons is positively related to the experience of crowding and that, with the number of persons controlled for, the number of rooms is negatively associated with the experience of crowding. These assumptions are untested and other views are plausible. For example, an excess of demands may be almost totally a product of the number of obligations one has toward others in the household and the number of rooms may be virtually irrelevant. In this case the number of persons would be a better measure of crowding than P/R as it would be both more direct and less contaminated. Furthermore, it has been argued by Baldassare (1978) that most of the apparent effects of crowding he found are actually due to the fact that crowded households tend to have large numbers of children. It appears to be his position that the effects of children are not due to their impact on household crowding but to other factors, and that controlling for the number of children would demonstrate that the correlation between crowding and other dependent variables is spurious. While not wanting to entirely rule out this possibility, we believe that a good case

can be made that to the degree children are associated with crowding much of their impact on others is due to the fact that they create a crowded household. Furthermore, such statistical controls are problematic for, in controlling for the number of children when looking at the relationship between P/R and a dependent variable, one is statistically eliminating most of the variance in P/R (i.e., one is using as a control variable a measure that is very highly correlated to the independent variable one is trying to look at). Nevertheless, it is clearly important to attempt to ascertain the validity of P/R as an objective measure of crowding.

In our analysis of the relationship of P/R to the lack of privacy scale and the felt demands scale we also looked at the relationships with number of persons, number of rooms, and a variety of other variables. From this analysis it was clear that P/R overall appeared to be the best objective predictor of the subjective experience of crowding. However, it was also clear that many of the variables we were looking at were so highly intercorrelated that it was impossible to come to any definitive conclusions. For example, among the full sample, for (a) P/R and number of persons, $r = .801$; (b) P/R and number of rooms, $r = -.025$; and (c) number of persons and number of rooms, $r = .505$. Obviously, although persons and rooms are highly intercorrelated, most of the variance in P/R is due to the number of persons. In looking only at respondents with children, the following correlations were obtained: (a) P/R and number of children, $r = .830$; (b) P/R and number of rooms, $r = -.376$; (c) number of persons and number of rooms, $r = .142$. Obviously for this group crowding is almost redundant with the number of children. We would note that the comparatively weak relationship between rooms and children suggests that when there are a large number of children they tend to share bedrooms. Because of the inability to draw definitive conclusions regarding P/R due to the high collinearity between P/R and number of persons and number of children, we looked at the relationships for these variables across our set of dependent variables to see if there was a justifi-

people really do care what happens to the next fellow; (4) this world is run by the few people in power and there is not much the average person can do about it; (5) there are so many ideas of what is right and wrong these days it is hard to figure out how to live your life; (6) most people are just naturally friendly and helpful; (7) it doesn't matter how hard you try, most of what happens to you is a matter of fate; (8) things are changing so fast these days one doesn't know what to expect from day to day; (9) you hardly ever feel awkward and out of place; (10) you seem to have a lot of control over what happens to you.

cation for using P/R as our objective measure of crowding. The analysis of these relationships for mental health is presented in Table 2.

A comparison of the number of persons and the number of rooms entered separately and jointly shows the predicted effects for six of the mental health variables. That is, the relationships with (a) number of persons and (b) number of rooms are discernibly increased when the other variable is used as a control. In the case of *nervous breakdown* controlling has no effects. In the case of *manifest irritation* controlling has no effect on the relationship with the number of persons but reduces the relationship with the number of rooms: As the number of persons and number of rooms are highly intercorrelated the typical effect of jointly entering both variables would be to reduce the individual relationships. As this generally does not happen with these data this provides fairly strong support for the view that the effects of (a) number of persons and (b) number of rooms are mediated by each other. A comparison of P/R and number of persons entered separately and jointly shows that with six of the eight mental health variables, after joint controls, the relationship with number of persons reverses and is now in the unpredicted direction, and in the case of *self-esteem*, significantly so. Furthermore, in each of these cases the size of the Beta associated with P/R increases when both variables are jointly entered. With *nervous breakdown* in all comparisons the Betas are in the predicted direction and controls reduce the size of both. However, in both comparisons the Beta with P/R is larger than that with number of persons. All of these measures deal with some aspect of the respondents' general mental health and the analysis provides strong support that for these variables P/R is a much better measure of crowding than number of persons. In the case of *manifest irritation* that pattern is just the reverse. This could be interpreted as a fluke (remember the very high collinearity between the variables). However, we are inclined to interpret the differences as real. Acts of *manifest irritation*, much more than the other variables, are probably

much more reactive to the number of persons one interacts with and the number of actual obligations one has and are probably less affected by spatial arrangements.

Now let us turn to a comparison of only those respondents who have children and look at the effect of P/R as compared with the effect of number of children. Before joint controls in seven of the eight relationships, number of children is statistically significant in the predicted direction. However, after controls none of the relationships is statistically significant in the predicted direction, three of the relationships have reversed sign and, in fact, the relationship with *self-esteem* now has a statistically significant relationship in the "wrong" direction. In contrast, seven of the relationships with P/R are statistically significant before joint controls and after controls five of these remain statistically significant. Furthermore, the sign of all of the relationships after joint controls remains in the predicted direction. Taken as a whole, these data clearly suggest that P/R is the best overall measure of crowding. Similar analysis with the other dependent variables also support this conclusion.

The detailed data on mental health are presented in Table 3. Before turning to substantive relationships, a few comments on the mode of analysis are warranted, as it is somewhat atypical. The first column in each table simply presents the zero-order correlation between the independent and control variables and the dependent variable. The second column presents Betas associated with each of the crowding variables when only the control variables are entered. The reason the three crowding variables were not entered simultaneously for this analysis is due to the issue of collinearity. Not only is P/R strongly related to lack of privacy and felt demands but we predicted that subjective experience of crowding would often interpret the relationship between P/R and the dependent variables and consequently this relationship should frequently be markedly reduced when lack of privacy and felt demands are added as controls. In addition, the lack of privacy scale and the demands scale are strongly correlated with each other ($r = .495, p < .001$). In

* Unpredicted direction.

short, if we entered the three crowding variables into the analysis at the same time, the apparent effect of both the individual variables and the overall effect of crowding would be less than the actual effects (e.g., Gordon, 1968). The third column presents the Betas with all crowding variables entered. This column serves two purposes. First, it allows us to ascertain whether the experience of crowding, as measured by demands and lack of privacy, does act as an intervening link between persons per room and the dependent variables.⁷ Second, it helps give an idea of the relative importance of the two components of the experience of crowding. The second part of the table presents the total explained variance (r^2) and the proportion of that variance that is uniquely explained by (a) the five control variables, (b) the three crowding variables, and (c) the proportion of variance that is collinear with both the control variables and the crowding variables.

As the data in Table 3 show, after controls the crowding variables are related to experiencing psychiatric symptoms, lacking a positive affect, having a nervous breakdown, experiencing manifest irritation, feeling alienated, having a low self-esteem and feeling unhappy. These relationships are statistically significant for all mental health items with all the crowding indices, except for the relationship between felt demands and positive affect. In most instances the subjective experience of crowding is related more strongly to the mental health measures than P/R. With all the mental health measures except positive affect and to some extent alienation, when the three crowding variables are simultaneously entered into the analysis the relationship with persons per room is greatly reduced. This suggests that the experience of crowding, as opera-

tionalized by the demands scale and lack of privacy scale, acts as an intervening variable between persons per room and the mental health variables. Overall the effects of lack of privacy and felt demands are relatively comparable. Taking an overall average shows that the three crowding variables uniquely account for 37.7% of the total explained variance, the six control variables uniquely account for 44.6%, and 17.7% is collinear.

Social relations in the home. The present data show that overcrowding is associated with irritability, withdrawal, weariness, ineffectual behavior and a variety of indicators of poor mental health. From these effects, it would follow that crowding should be related to poor social relationships in the home. The literature provides support for this premise (Loring, 1955; Reimer, 1945; Galle et al., 1972; Galle and Gove, 1977; Mitchell, 1971; Baldassare, 1978; Booth and Edwards, 1976), but there are serious methodological problems with many of these studies as well as substantial variation in the degree to which crowding appears to have negative effects on family relationships.

In our analysis we look at four measures of marital relations (998 respondents were married), one measure of the respondents' relationship with their children (776 respondents had children), and one measure of relations with others living in the home (580 respondents had others living in the home). To measure marital relations, we used a subset of the items in Ogden and Bradburn (1969) to create a scale measuring *good marital relations*⁸ and another subset to create a scale measuring *poor marital relations*.⁹ These scales were z-scored and then combined to create a

⁷ Following Blalock (1972), most sociologists use partial correlation coefficients where we have used standardized regression coefficients to test for intervening variables. We would simply note that, since the significance test used in the SPSS statistical package utilized here (Nie et al., 1975) for testing our regression coefficients is mathematically identical to that offered by Blalock to test for the significance of partial correlation coefficients, the procedure we use is virtually the same.

⁸ We asked whether in the past few weeks the respondent and his or her spouse had (1) had a good laugh together or shared a joke, (2) been affectionate toward each other, (3) spent an evening just chatting with each other, (4) visited with friends, and (5) done something the other particularly appreciated.

⁹ We asked whether in the past few weeks the following had caused differences of opinion or created problems in their marriage: (1) being too tired, (2) having irritating habits, (3) spending money, (4) being away from home, (5) deciding what to do with free time.

marital relations balance scale. The fourth measure of marital relations was the question, "How close are you and your husband/wife? (very close, fairly close, not too close or not at all close)." The measure of the respondents' relationships with their children¹⁰ was the question, "All in all, how well would you say you got along with (name of child)? (very well, pretty well or not too well)." The measure of how well respondents got along with other persons living in the home involved the same question except for substituting the others' names. The respondents also were asked, "During the past year have you been involved in any arguments in the home? (yes, no)." This question was followed by asking if any of the arguments were serious and then asking, "Did any of these arguments lead to physical blows? (yes, no)."

These data are presented in Table 4. Looking at marital relations shows that, after controls, the three indices of crowding are related significantly to a lack of positive marital relations, the presence of negative relations, a low score on the marital relations balance scale, and not feeling close to one's spouse. Looking at the respondents' relationships with their children shows that persons per room is unrelated, while lack of privacy and felt demands have significant adverse effects. The pattern for the respondents' relationships with "others" is the same: persons per room is not significantly related, while lack of privacy and felt demands have strong negative relationships. Persons per room is unrelated to arguments in the home, while lack of privacy and demands are strongly related to having arguments. Perhaps the most consistent finding in the animal literature is that crowding is associated with aggressive behavior. The present data are consistent with this literature for, after controls, each of the three indices of crowding has a statistically significant relationship with physical violence in the home.

Comparing the effects of crowding with

those of the five control variables shows that crowding tends to explain more variance. On the average, the crowding variables independently account for 51.1% of the total explained variance, the control variables account for 39.1%, and 9.8% is collinear. As with the mental health variables, the data indicate that the two indices of experienced crowding, felt demands and lack of privacy, generally act as intervening variables "explaining" the relationship between persons per room and crowding.

Social relations outside the home. It would seem that crowding in the home would have a relatively slight effect on social relationships occurring outside the home, particularly in comparison to its effect on social relations in the home. However, if, as our data suggest, crowding has an effect on the mental state of the individual, we would expect it to have some effect on social relationships outside the home. Furthermore, visiting with others (friends, neighbors, relatives) often occurs in the home and one might expect crowding to have an effect on such visits. In our analysis we look at the respondents' relationships with their neighbors, relatives, and friends and at their involvement in arguments and physical violence outside the home. In every case crowding in the home had a statistically significant effect on these indicators of social relationships outside the home but, as anticipated, its effect relative to the control variables is minor.¹¹

Physical health. In the medical literature there is a long tradition of relating crowding and poor housing to morbidity and mortality and in general these studies report a fairly strong relationship between crowding and morbidity and mortality (Galle and Gove, 1978). Most of these studies are limited by the fact that they use ecological data, although a few use individual data (Gordis et al., 1969; Wilner et al., 1962; Booth and Cowell, 1976; and Baldassare, 1978). In many respects the Toronto study contains the best data, for its major emphasis was on physical health and the respondents received a detailed

¹⁰ This question was actually asked with regard to only one preselected child; for information with regard to this procedure see the section below on child care.

¹¹ The table presenting these data is available upon request.

physical examination. Booth and Cowell (1976:218), on the basis of their analysis, conclude that "crowded household and neighborhood conditions have very little or no effect on people's health." However, not only was the Toronto study generally flawed by serious methodological problems (Gove and Hughes, 1979b), but in addition there was a 49% attrition between the interview and the physical examination (Booth and Cowell, 1976:207), and a number of persons did not receive a physical examination because they were too ill to travel to the examination center. Furthermore, we are inclined to interpret their data as showing more of a relationship than they do. For example, after controlling for age, income, education, ethnic origin, parent's health, subjective household crowding, objective neighborhood crowding and subjective neighborhood crowding, they found 54% of the men who lived in crowded households had a stress-related disease, as compared with 34% of the men living in uncrowded households (Booth and Cowell, 1976:216). Nevertheless, as they suggest, the relationship between crowding and health may not be as strong as the ecological literature would indicate.

The present study did not focus on physical health and thus our data rely on the respondents' self-reports. The literature suggests that, if crowding is related to physical health, it is because persons in crowded households are physically run-down, more susceptible to infectious disease and, when sick, are involved in a flow of activities and consequently cannot get a good rest and are not well cared for (e.g., Galle et al., 1972; Schorr, 1966). In the interview we obtained information on all of these presumed relationships. The respondents were asked: "(1) Do you think you get enough sleep? (2) If someone else at home is sick with a bug, do you often seem to catch it? (3) When you are *really* sick, are you almost always able to get a good rest? (4) Even when you are *really* sick, are there a number of chores that you just have to do? (5) When you are *really* sick, is there someone to help take care of you?" To obtain an indicator of the respondents' health, we asked each one, "Would you say your overall health

is excellent, good, fair or poor?" We would note that the five measures of the presumed link between crowding and health are all significantly related to respondents' overall evaluation of their health (Gove and Hughes, 1979a).

The data on crowding and physical health are presented in Table 5. First, let us look at the variables linking crowding to physical health. All the relationships with felt demands and lack of privacy are statistically significant, with the relationship with felt demands consistently being the strongest. Persons per room has the weakest relationships, with only two being significant. The relative effect of the three crowding variables is quite strong. On the average, they independently account for 45.5% of the explained variance, the control variables independently account for 32.8%, and 21.9% is collinear. Turning to the respondents' evaluation of their overall health, we find that each of the crowding variables has a significant negative relationship with the respondents' health. The control variables, however, independently explain considerably more variance than the crowding variables. In general, the data are consistent with the premise that lack of privacy and felt demands tend to act as intervening variables interpreting the relationship between persons per room and the respondents' physical health.

Care of children. A very common finding in the animal studies is that crowding is related to the ineffectual care of offspring (Galle and Gove, 1978). Relatively little attention has been paid to the effects of crowding on child care, however. The literature that does exist consistently indicates that crowding has adverse effects (Galle et al., 1972; Galle and Gove, 1977; Reimer, 1945; Mitchell, 1971; Booth, 1976; Baldassare, 1978; Loo, 1972). We assumed that if crowding had an adverse effect on parental care it would be due largely to the parents' experiencing their children as underfoot, noisy, and demanding. We felt that parents who experienced their children in this manner would be aggressive towards them, unsupportive, and relatively unconcerned with their behavior outside the home. We developed a scale of the extent to which the respon-

dents felt harrassed by their children.¹² These items were asked of all respondents with children under 18 in the home ($n = 776$). As is shown in Table 6, all three crowding variables are strongly related to parents feeling harrassed by their children. The respondent was also asked, "How often is it a relief when your children are out of the house? (often, sometimes, never)." As would be anticipated, the crowded respondents indicated considerable relief when the children were out of the house.

In the remainder of this section the questions deal with a specific preselected child. This child was selected by choosing the one whose age was closest to thirteen years. We felt that by focusing on a specific child we would get more exact information, and that the years clustering around thirteen tended to be particularly crucial in parent-child interactions (for arguments supporting these decisions see Booth, 1976; Baldassare, 1978). As parents who experience crowding felt harrassed by their children and tended to have a poor relationship (see Table 4), one would anticipate that they would tend not to be parents who were warm and considerate. The parents were asked: "How often do you physically punish _____? (often, sometimes, never);" and a set of four questions,¹³ which were scaled, dealing with supportive behavior. As Table 6 shows, after controls, P/R and felt demands were significantly associated with physically punishing the child and P/R was associated with a lack of supportive behavior. However, the overall effect of the crowding variables was relatively slight,

particularly in comparison to the effects of the control variables. In short their reported interaction was more supportive than might be anticipated. This suggests that the societal norms regulating the parents' interaction with their children tend to override the effects of crowding. If this is correct, then contrary to Baldassare (1978), children do not suffer disproportionately due to their lack of power. In fact, societal norms may create a form of social immunity for children in a crowded environment and as a consequence children may contribute disproportionately to the experience of excessive demands and lack of privacy by adults.

As an indicator of their awareness of their child's involvements away from the home the parents were asked: "(1) In general, how well do you know _____'s friends (very well, pretty well or not too well), and (2) in general how well do you know the parents of _____'s friends? (very well, pretty well and not too well)." Table 6 shows persons per room has a fairly strong negative relationship with both knowledge of playmates and their parents, while felt demands and lack of privacy have a modest negative relationship with knowledge of playmates.

One of Booth and Johnson's (1975) findings was that children from crowded homes do not do as well in school. A likely reason for this is that such children would not have a place to study. In the interview the parents were asked, "Does _____ have a place at home where he/she can read or study in quiet?" As Table 6 shows, the three crowding variables are strongly related to the lack of such a place, with the relationship being strongest with persons per room. A separate question asking if the child has "a place at home that is away from others where he/she can play or spend his/her time" shows even stronger relationships with the crowding variables.

In summary, in crowded households children are experienced as an irritant and it is a relief when they are out of the home. In such households children lack privacy and a place to study, and it would seem that this would create problems for children and tend to push them out of the

¹² The items were: "(1) How often do your children get in your way? (2) How often do you get upset because your children are too noisy? (3) How often do you feel as if your children are making too many demands? (4) How often do you wish you could get away from your children?" The response categories were often, sometimes, and never.

¹³ The items were: "(1) How often do you have a heart to heart talk with (name of child)? (2) How often do you compliment (name of child), that is, tell him/her how good he/she is or what a good job he/she has done? (3) How often are you able to help (name of child) when he/she is unhappy? (4) How often do you actually tell (name of child) that you love or care about him/her?" The response categories were often, sometimes and never.

* Relationship in unpredicted direction.

home. Furthermore, parents in crowded households are less informed about their children's activities outside the household. In short, there is considerable evidence that for children household crowding results in a very problematic environment. On the other hand the data indicate that crowding is related only weakly to physical punishment and a lack of supportive behavior. On the average the crowding variables independently accounted for 45.5% of the explained variance and the control variables independently accounted for 44.7%, with 8.7% of the variance being collinear.

DISCUSSION

One of the most important characteristics of our sample is that its levels of crowding are typical of those in the United States. In addition the characteristics of the sample are generally similar to those of the population of Chicago. Furthermore, the effects of crowding are linear, that is, the effects are not primarily due to extreme reactions at very high levels of crowding. As a consequence, the results of this study have clear implications for the general population. The analysis suggests the following conclusions:

1. Persons per room (P/R) is a good objective measure of crowding.
2. The experience of crowding largely involves the experience of excessive social demands and a lack of privacy.
3. Crowding results in physical withdrawal, psychological withdrawal, a lack of effective planning behavior, and a general feeling of being "washed out."
4. The experience of crowding is strongly related to poor mental health.
5. The experience of crowding is strongly related to poor social relationships in the home.
6. The experience of crowding is strongly associated with a number of characteristics of poor child care, although it is only moderately associated with poor interaction between parent and child.
7. The experience of crowding is associated with poor physical health by being strongly associated with the following:

generally getting insufficient sleep, catching infectious diseases, having to do chores, being unable to get a good rest, and not being cared for by others when one is sick.

8. The experience of crowding is significantly associated with poor social relationships outside the home, but the effects of crowding are modest.

9. The effects of crowding as measured by P/R tend to be largely explained or interpreted by the experience of excessive demands and lack of privacy. This is particularly true with regard to poor mental health, poor social relationships in the home and poor physical health.

10. The theoretical literature suggests that excessive demands and lack of privacy are the key components of the experience of crowding. In the present data the strength of the effects of these two variables are quite similar, suggesting they both play an important and fairly comparable role in the experience of crowding.

In a number of places we have referred to the relationships with crowding as being fairly strong and the person unfamiliar with the use of multiple regression with individual data may view such statements inappropriate. A great deal of data published by sociologists present relationships that are much stronger; however, these analyses almost invariably use aggregate data which almost always greatly inflates the size of the correlation.¹⁴ Data on individuals are often presented in tabular form and a difference of 20% may look very large, particularly if it is on the end of a continuum (5% vs. 25%). But when such data are analyzed by multiple regression, the relationships rarely exceed those of the present study. As the size of a relationship is determined largely by the nature of the data (whether it is aggregate or individual, the amount of

¹⁴ For example, looking at the effects of crowding in the same city and using fewer variables, r^2 's above .80 were routinely produced with the use of aggregate data (Galle and Gove, 1979). Whereas in the present study we only infrequently have an r^2 over .15.

¹⁵ As the variables used are generally similar the difference in the amount of explained variance is almost entirely due to the use of aggregate as compared with individual data.

variance possible, the skewness of the distribution, etc.) there cannot be a general rule which indicates whether a relationship is strong or weak. Perhaps the best criteria for deciding whether a relationship is strong is by comparing it with other independent variables which we know (or at least believed) to be important (i.e., powerful predictors). Fischer et al. (1975:415) stated the effects of crowding seem "trivial compared to race, sex, education, income and the like." We have taken these four variables and added age and marital status and used them as controls. As our analysis has shown, the experience of crowding, on the average, uniquely explains approximately as much variance as is uniquely explained by the combined effects of these six control variables. In short, crowding does have substantial effects and it is time to turn away from the question of whether it ever has effects to the study of the factors which magnify or minimize its effects. In particular we need to look at (1) the norms that regulate demands and privacy, and how these norms may vary by one's roles and social situation; (2) the effects of household composition on the experience of crowding; and (3) the interaction of household crowding and the macroenvironment.

TOWARD A CLASS-DIALECTICAL MODEL OF POWER: AN EMPIRICAL ASSESSMENT OF THREE COMPETING MODELS OF POLITICAL POWER*

J. ALLEN WHITT

Brown University

American Sociological Review 1979, Vol. 44 (February):81-100

The paper outlines the characteristics of three competing models of political power: pluralist, elitist, and class-dialectic. The latter model has been neglected by mainstream sociology, particularly at the empirical level of the community. Using systematic case studies of five related political decisions, this study assesses the relative explanatory power of the three models. The analysis demonstrates that the class-dialectic model is highly useful and that it deserves to be treated as a serious guide to studies of political power.

Over the last two decades a central issue within political sociology in the United States has been the debate over the relative merits of the pluralist and elitist models of the political system. A review of that debate is not the purpose of this paper. Rather, this work aims to accomplish two things. First, it develops a third model of the political system, a class-dialectical model, that has been largely obscured by the pluralist/elitist controversy. Second, this paper attempts to demonstrate empirically the cogency and explanatory power of the dialectic as compared with either pluralist or elitist interpretations.

That the pluralist/elitist debate has tended to eclipse the dialectical model is paradoxical since (as an explicit political model) the latter has the longest historical roots of the three. Having its origin in the works of Marx, it has been elaborated by later writers, particularly contemporary

neo-Marxists. Although certainly not ignored in theoretical work, nor within European sociology, the class-dialectical model has not been treated by mainstream sociology in the United States as a serious contender at the *empirical* level traditionally addressed by most pluralist and elitist studies, particularly the *community* level (cf. Aiken and Mott, 1970; Bonjean et al., 1971; Hawley and Wirt, 1974). There are two reasons for this relative lack of attention given to the class-dialectic model as a guide for empirical research. First, the polarization resulting from the controversy has given rise to the tendency to collapse categories and to treat the class-dialectic and elitist models as equivalent. This blurring of important distinctions between the two models has confused and oversimplified the theoretical issues and has resulted in a general loss of explanatory power of political system models. Secondly, much of the pluralist/elitist debate has been developed around empirical studies of political power at the community level. Researchers who have used the class-dialectic model, focusing usually on the national or international level, have left the important area of community as virtually exclusive domain of pluralist and elitist approaches.¹ Since it appears that the

The following people have read an earlier version of this paper. I am most grateful for their valuable suggestions and insightful criticisms. They are (speaking as one who has always been stuck at the end of the alphabet): T. R. Young, Jane Weiss, Michael Useem, Theda Skocpol, Joyce Rothschild-Whitt, Maynard Robison, Jack Roach, Nelson Polsby, Roland Pellegrin, James Mulherin, Scott McNall, G. William Domhoff, Steven Deutsch, William D'Antonio, Fred Block and Howard Aldrich. In addition, the three anonymous reviewers for *ASR* provided helpful comments.

¹ The main reason for this focus on different levels is that, as Alford (1975:150-2) points out, the class model generally has been concerned with the societal context of action, while the pluralist and elite models

community level has historically become established as the touchstone for developing and testing presumably general models of political power, the class-dialectic model has largely been overlooked by researchers.

This paper proceeds in the following order. First, the three theoretical models are described and clarified. Next, a set of general hypotheses are derived from each model. Finally, a series of case studies of political events is analyzed in order to demonstrate the relative explanatory potentials of the three models.

THEORETICAL CHARACTERISTICS OF MODELS

Table 1 presents in summary fashion the essential characteristics of the pluralist, elitist, and class-dialectic models.² Since

have tended to look at the individual and organizational contexts, respectively. Therefore, the latter two models have been more readily applicable at the level of community power analyses.

² These characteristics represent a distillation of a great deal of literature for each of the three models. As this categorization is a shorthand way of summarizing the basic outlines of the three models, it is not possible here to review this extensive literature, nor to discuss subtle differences, ambiguous cases, and so on. It is also possible in so complex a subject to classify political models in different ways and to emphasize somewhat different characteristics for each of the models. Thus, Alford (1975) refers to "paradigms" instead of models, and labels them pluralist, elite, and class. Although my own classification was developed independently, there are strong similarities. There are, however, at least two major differences between my scheme and Alford's. First, his aim is to categorize the paradigms relating the "relations between the state and the society" (emphasis added). I am not directly concerned with the state, but with how one discovers the *locus of power* in the society or community. Second, my analysis holds that the concept of the dialectical nature of power (stemming from the existence of systemic contradictions) is central to the class-dialectic model. Alford does not present this as a feature of his "class" paradigm.

Esping-Andersen et al., (1976) have developed a classification of four "perspectives," again concerning conceptions of the functioning of the state. These they call the pluralist, instrumentalist, structuralist, and political class perspectives. This classification varies from my own (for reasons that will be explained) but parallels it quite closely, although in this case too my analysis was developed independently. Here they do stress the dialectical nature of power, with class political struggle seen as both limiting

the pluralist model was developed in response to the elitist model it will be convenient to start with the latter model.

The Elitist Model

According to the elitist model, political power is held to be concentrated in the hands of elites who occupy the top positions in large and increasingly centralized institutional hierarchies. Elites tend to be unified in purpose and outlook because of their similar social backgrounds and because of a convergence of interests arising from their positions within dominant social institutions. The goals of elites are reflected directly in the actions of the state which has little, if any, autonomy relative to elite goals and interests. Elites almost invariably get their way whenever important public decisions are made, and social conflicts, when they occur, are managed by elites in such a way as to produce outcomes favorable to their interests. As a consequence, there are no clearly identified limits to elite power and the distribution of power is essentially stable.

The Pluralist Model

Initially developed by Dahl (1961) in its modern and systematic form as a response to Mills (1956) and Hunter (1953), the pluralist model starts with interest groups as the basic features of organized political life. The power (or influence as most pluralists prefer to call it) of private groups is based mainly on the effective political organization of voluntary associations, but also is a function of such

dominant class actions and producing modifications in the structure of the state. The main purpose of the work is to demonstrate that it is possible to think of the state not simply as an instrument of a ruling elite or as determined by systemic contradictions, but as "an object of class struggle" in its own right (Esping-Andersen et al., 1976:190). This is a useful perspective which deserves empirical research. However, for purposes of this work roughly what they call the structuralist and class perspectives will be treated as one category, the class-dialectic. The similarities between the two perspectives are many, and such a distinction is not necessary for the present analysis which is concerned not with the state, but with comparing the class-dialectic model on the one hand with the pluralist and elite models on the other.

Table 1. Characteristics of Models

	Pluralistic	Elite	Class-Dialectic
Basic units of analysis	Interest groups	Institutional elites	Social institutions; social classes
Essential processes	Interest group competition	Hierarchical dominance by elites	Imperatives of social institutions; class domination and conflict
Basis of group power (resources)	Many bases: organizational, governmental, economic, social, personal	Institutional position, common social background, convergent interests	Class position; degree of class consciousness and organization
Distribution of power	Dispersed among competing, heterogeneous groups	Concentrated in relatively homogenous elites	Held by dominant class, but potentially available to subordinate classes
Limits and stability of groups' power	Unstable; limited by democratic value consensus, shifting strength among organized interests and by cross-cutting allegiances	Stable, no identifiable limits to elite domination	Historically contingent; generally stable, but limited by class conflict and contradictions within and among social institutions
Conception of role of the state	State is a broker, able to preserve some autonomy by balancing competing interests	State has little, if any, autonomy; captive of elite interests	State serves interests of dominant class, but requires a degree of autonomy from segments of dominant class in order to act to preserve basis of class hegemony

individual qualities as the political strategies and leadership abilities of party and group leaders. A key concept is competition. Competitive relationships among the many diverse interest groups that make up society, along with the existence of cross-cutting allegiances held by group members, have the effect of dispersing power over a wide range of organized groups. The distribution of power is essentially unstable since interests and alliances are typically rather short-lived, and new groups and coalitions are continually being organized as old ones decline. There are limits on the power of any one group. This is true by virtue of the necessity for compromises with other groups and because of the existence of a basic value consensus which stresses adherence to democratic norms and values. The state is influenced by the demands of powerful organized interest groups but also is able to serve its own ends and to achieve substantial autonomy by operating as a

broker or balancing agent among the competing groups.

The Class-Dialectic Model

The class-dialectic model holds that political processes must be understood in terms of the institutional structure of society and in terms of the relation of social classes to each other. The manner in which the basic institutions of society (especially the economy) are organized has crucial implications for not only the general character of society but also for how classes relate to each other and how political and social power is exercised. The structure of social institutions places restraints and limits on the behavior of groups within the society. In order to comprehend politics, then, one must understand how the imperatives of social institutions shape the behavior of classes and individuals. To focus only upon the

immediate *decisional* and *behavioral* aspects of politics (as do most researchers) is to fall into the trap of what Lukes (1974:22) calls "methodological individualism." One must be aware not only of the possibility of suppression of political issues (Bachrach and Baratz, 1962) by dominant classes, but also of the political implications of strategically allowing the bias of social *institutions* to determine political outcomes with *no* observable decisions or actions, *as such*, being required of dominant political actors. The class-dialectic model argues that one must understand the logic and biases of social institutions as well as the observable political behaviors of social classes and individual actors. There is a mutually reinforcing relationship between social institutions and dominant classes: dominant classes act to preserve those institutions which are the basis of their own hegemony. Institutions shape behavior (of both dominant and subordinate classes) and the dominant class often shapes institutions.

Capitalist societies are characterized by the presence of a dominant class which controls the means of production. This control is the basic resource for power in the society. With it comes the ability to shape the more superstructural institutions of society, including the ability to carry out ideological hegemony (Miliband, 1969) and generally to manipulate the societal context in which political contests are waged. Other resources for power are the degree of class-consciousness and extent of class political organization. The state functions to serve the interests of the dominant class by preserving the bases of class hegemony. However, power is potentially available to the subordinate classes if they become sufficiently class-conscious and politically organized to wrest control or to challenge the control of the means of production. Thus, the power of the dominant class is not absolute. This is even more true because (1) there are not only interclass conflicts, but also intra-class conflicts among capitalists, and (2) there are contradictions within the economic and class structure that produce disruptions which may limit the ability of

the dominant class to act.³ It is this *dialectical*⁴ conception of power, of the relations between social classes, and of history that is the most important difference separating the elitist and class-dialectic models.

Overall the most salient differences among the three models are these. The elitist and class-dialectic models use much larger units of analysis than does the pluralist model. The former two models also hold that power is much more concentrated than is true in the pluralist model. The pluralist model says that power relations are quite unstable while the elitist model presents a very stable picture of power relations. The class-dialectic model conceives of power as much more stable than in the pluralist model, but somewhat *less* stable than in the elitist model. Interestingly, differences concerning the role of the state are clearest between the pluralist and elitist models: the pluralist state has autonomy, the elitist state does not. It is not possible to classify the class-dialectic position on the issue of state autonomy in a simple way,⁵ although it is held that the state serves the interests of the dominant class.

³ For example, an economic crisis may not only erode the economic basis of class hegemony, but also may make social control more difficult by weakening the legitimacy of dominant institutions. O'Connor (1973) argues that the current "budget crisis" of the state may produce these same effects.

⁴ The concept of the dialectic is rooted in the works of Aristotle and certain pre-Socratic philosophers, but is mainly associated with Hegel. Marx substantially modified the concept in his own work (Zeitlin, 1968:89-94). As used here, following essentially the use of Marx, it refers to history as a continual process of unfolding. Social institutions, economic systems, and political institutions contain inherent contradictions. These produce conflicts and strains that eventually lead to the transformation of those institutions and systems. *Contradictions* are thus the engine of social change, and their analysis is central also to understanding the dynamics of political power.

⁵ There is currently a debate among proponents of the class-dialectic view as to how the state should be conceived. One view is close to the power elitist position: the state acts directly in the interests of the dominant class and will not act to damage the interests of any large segment of that class. There is little or no state autonomy. On the other hand, the second view holds that the state *must* have a certain amount

EMPIRICAL APPLICATION OF MODELS

Generation of Hypotheses

We are now in a position to derive the following general hypotheses from each of the models.

Plural hypotheses. If the pluralist model is correct, the study of an important political issue should reveal (1) the active involvement of numerous interest groups, (2) divergent goals and interests among the groups, (3) a vigorous, competitive relationship among the groups, (4) interests and alliances that shift over time, and (5) political outcomes that consistently favor no particular group more than others.

Power elitist hypotheses. If the power elitist model is correct, the study of an important political issue should reveal (1) a high degree of elite involvement, (2) general convergence of interest among elites, (3) elite unity and dominance on the issue, (4) stability of political allegiances, and (5) outcomes that tend to favor elite interests.

Class-dialectic hypotheses. If the class-dialectic model is correct, the study of an important political issue should reveal (1) biases of social institutions that favor outcomes beneficial to dominant classes; (2) evidence of latent class conflict (divergent interests) or observable class conflict over the issue, perhaps including intraclass conflicts among the dominant class, but accompanied by attempts to achieve class unity and cohesion; (3) political alliances and stability of power relations that are historically contingent, reflecting the need to respond to inter- and intraclass conflicts and structural crisis; and (4) outcomes that usually favor dominant class interest, but may

also reflect the power of opposing classes and the limitations imposed by structural contradictions.

The goal here is not to test these hypotheses in a formal sense. A systematic test would require a detailed analysis of a number of important political issues, at different levels of inclusiveness (that is, local, regional, and national), over a significant span of time. That is beyond the scope of this research. Rather, this study seeks to use a set of case studies in a specific issue-area to illustrate the relative usefulness of the three models for understanding political processes at the community level and for providing guides for further theoretical elaboration and research. In short, it aims to be suggestive rather than definitive.

Methods of Research and Selection of Issues

Two related points of contention have been at the center of recent pluralist/elitist controversy: (1) the research methods to be used, and (2) the criteria to be used in selecting a political issue for study. Bachrach and Baratz (1962), for example, have argued that the pluralist decisional method is biased in that it does not allow for the possibility of deliberate suppression of issues. Walton (1970) has shown that the kind of power structures discovered in community studies appears to be partly an artifact of the specific methods utilized, with decisional methods tending to uncover pluralistic structures, and reputational methods finding elite power structures.

The strategy employed here is as follows. Since there is little agreement in the field as to what constitutes an "important" issue, and no clear consensus as to the most appropriate method for doing research, an issue was chosen and methods were utilized which appeared to satisfy the criteria clearly acceptable to at least one of the three perspectives. In this case, it was decided to conform to pluralist methodological requirements. If it is true that the use of pluralistic criteria will bias results toward pluralistic findings, the following caveats must be kept in mind when

of autonomy if it is to avoid getting captured by one group of capitalists. Should this happen, it would not be able to serve class interests in *general*, instead falling prey to intraclass disputes. Thus the state functions to preserve the capitalist system on behalf of the capitalist class. The first view also tends to argue that capitalists are capable of organizing as a class without the need of state assistance. The second view maintains the state is an essential feature of capitalist social organization and domination. Thus, the first view is similar to the elitist model while the second is more like the pluralist model in granting the state a degree of autonomy.

interpreting this study's results. First, should support for the pluralist model emerge, it cannot be ruled out that this is an artifact of study design. On the other hand, should findings support either the elite model or the class-dialectic model, we may have considerable confidence that they are not caused by biases in research methodology.

It was decided to follow the specifications of Polsby (1970:301) in designing this study. He writes:

First, the researcher should pick issue-areas as the focus of his study. Second, he should be able to defend these issue-areas as being very important to the life of the community. Third, he should study actual behavior, either at first hand, or by reconstructing behavior from documents, informants, newspapers and other appropriate sources. . . . The final recommendation is of the same order: researchers should study the outcomes of actual decisions within the community.

The issue area for this study is public transportation politics. The question of the importance of an issue-area under investigation is a crucial one. Transportation can be defended as an important issue on several grounds. The decisions examined herein (see Table 2) involved the allocation of large amounts of public monies among various competing transportation uses. All of the issues had implications for the construction of facilities that would have had considerable impact on patterns of transportation and land use, and on land values and economic activity in large urban areas. Many groups had material interests and stood to gain or lose. These were, in short, not merely "symbolic" issues, but "instrumental" issues that would "convey benefits to particular groups" (Edelman, 1967:2).⁶ Polsby's first and second recommendations are thus met.

The two final recommendations, that actual behavior and decisional outcomes be studied, are met by the research design. The methods employed are similar to

⁶ Also, pluralists treat transportation issues as important: Polsby (1970:298) asserts that importance, and Banfield (1961) uses the Chicago Transit Authority as the basis for a decisional case study.

Table 2. Summary of California Transit Elections

Issue	Date	Area	Proposal	Financing	Contributions		Outcome
					For	Against	
BART	Nov. 1962	Bay Area rail		\$792 million bond issue to be financed out of property taxes	\$203,000 from business	none	passed
Prop. A.	Nov. 1968	L.A. rail & bus		\$2.5 billion bond issue to be financed by sales tax	\$458,000 with 86% from business	\$25,000 from five contributions	failed
Prop. 18	Nov. 1970	Calif. divert 25% of highway funds		none required	\$18,000 in small contributions	\$348,000 from highway lobby	failed
Prop. 5	June 1974	Calif. divert 5-25% of highway funds		none required	\$203,000 with 99% from business	\$1,700 from auto club	passed
Prop. A.	Nov. 1974	L.A. rail & bus		sales tax to match federal funds	\$563,000 with 94% from business	none	failed

those used by Banfield (1961) with some essential modifications. As in Banfield's study, the decisions analyzed here were reported in the news media and constituted matters of public controversy. In fact, all five issues were electoral campaigns. Whereas Banfield based his study on one urban area (Chicago), this study broadens the definition of *community* to include the political boundaries of a state (California). This is done to allow the inclusion of electoral campaigns that were not restricted to large cities (as were Proposition A of 1968 and Proposition A of 1974, both in Los Angeles), or to urban regions (BART campaign of 1962 in the San Francisco Bay Area), but also involved statewide issues (Proposition 18 of 1970 and Proposition 5 of 1974). Together these campaigns constitute a coherent issue-area of interrelated transportation decisions affecting California and its major urban areas: they were the most important *public* decisions concerning transportation in the state between 1962 and 1974. This broader definition of community should pose no problems for pluralist theorists since the inclusion of a larger polity and a geographic and social area of such diversity would be expected to increase rather than decrease interest group plurality (cf. McConnell, 1966).

A more important departure from the Banfield method was to supplement interview data and media analysis with an examination of campaign contribution data. Media coverage was used to provide an initial list of persons and organizations reported to be active in the transportation campaigns. These people were contacted, interviewed concerning their roles in the campaigns, and asked to provide names of other active organizations and people. More interviews were then conducted. After several dozen interviews, it was clear that there was general agreement as to what groups and leaders had been active on both sides of the issues. This information was then checked against records of actual campaign contributions, a technique not used by most decisional researchers.⁷

However, the most important departure from methods such as those used by Banfield is the incorporation of a *longitudinal* study of several related public decisions over a considerable period of time (in this case, twelve years). Instead of studying only one decision occupying a relatively brief span of time, this *historical, multi-decision* approach made it possible to discover the dynamics of political involvement and to isolate patterns of political behavior not apparent over short intervals, as during one political campaign.

There appeared to be reasons for assuming, *a priori*, that the issue-area and specific cases selected for study would provide a rich source of data for explanation by the three models and might, in fact, constitute a crucial test, particularly for the differences between the pluralist model on the one hand and the elitist and class models on the other.⁸

legal and are recorded with the California Secretary of State. This provided a nearly unique opportunity. Contributions data are very important because they clearly show active, material involvement in electoral campaigns, and they provide a means of checking the validity of media and interview accounts identifying support and opposition. Using campaign contribution data as a means of studying the political process is an underutilized research technique, in spite of the general recognition of the significant impact of money in elections (cf. Alexander, 1976). Used together, these three sources of campaign involvement data (media accounts, interviews, and contributions) provided a consistent and comprehensive picture of active supporters and opponents of the issues studied.

⁸ In a number of ways, the issue-area selected for study and the political setting in which it was examined seemed to constitute a crucial test for the pluralist model of politics. Prior to the study, there were accounts of a reputedly powerful highway lobby operating at the national level which was generally successful in promoting legislation and public policies favorable to automobile-highway interests and in blocking development of effective alternative systems of urban transportation (Buel, 1972; Kelley, 1971; Leavitt, 1970; Mowbray, 1969; Snell, 1974). California's own highway lobby had been reported to be one of the most powerful and successful of those operating at the state level (Simmons, 1968). On the other hand, there was also reason to believe that, according to pluralist logic, a countervailing force (Galbraith, 1956) was coming into being that would compete with the highway interests and help to reduce the overwhelming dominance of the automobile as the mode of urban transportation in California. In the state, as was true nationally, there was much

⁷ Fortunately, for this study, California is somewhat atypical in that *corporate* contributions are

The Transportation Campaigns

The five campaigns studied are summarized in Table 2.⁹ Each will be discussed in turn, beginning with the earliest and one of the most important, the San Francisco Bay Area Rapid Transit (BART) campaign of 1962.

Bart campaign. The construction of the expensive and technologically sophisticated BART system was officially authorized by Bay Area voters in a bond election in 1962. However, for many years before that election, the chief force pushing for the establishment of a rail rapid transit system in the Bay Area was the Bay Area Council (BAC). This is an organization of the largest corporations in the Bay Area, headquartered mainly in downtown San Francisco. This advocacy by the BAC is confirmed by interview data, media accounts, by statements from the BAC itself, by previous research (Zwerling, 1974) and by campaign contributions. The BAC companies were early advocates of such a system, were instrumental in getting the California Legislature to create the San Francisco Bay Area Rapid Transit District in 1957, and took a very active part in organizing and financing the 1962 bond campaign for BART. The bonds to construct the system were to be paid for by local property taxes. As can be seen in Table 2, over \$200,000 was

discussion in the 1960s and early 1970s of the destructive aspects of the automobile on urban areas, and citizens' groups and urban politicians were advocating modern transport systems for California's cities. Most importantly, a decision had been made in San Francisco in 1962 to build the first wholly-new transit system in any city in the U.S. in over half a century. As of that time, the Bay Area Rapid Transit (BART) system was said to be the most expensive, privately engineered project in U.S. history. Generating millions of dollars worth of construction work and requiring enormous quantities of expensive, high-technology components, it was clear that transit industry suppliers, for example, stood to gain much from BART's construction. *Was the rise of BART an indication of a nascent rapid transit interest group that would countervail against the economic and political power of the California highway lobby?* If not, what was the nature of the political forces that produced BART? Research was initially undertaken to determine the identity of the interests that actively supported the campaign for BART.

⁹ For a detailed description and analysis of the five campaigns, see Whitt (1975).

contributed in support of the BART campaign, the sum apparently coming virtually exclusively from the BAC COMPANIES.¹⁰ Executives from downtown banks and financial institutions played particularly active roles in organizing the pro-BART electoral campaign. The system was sold to voters by using symbolic appeals: BART would dramatically reduce traffic congestion on major traffic routes, such as the San Francisco-Oakland Bay Bridge, and would alleviate air pollution. Pre-BART planning documents, interviews with business leaders, and publications of business groups after the election make it clear that the main business supporters of BART were more concerned with the system's presumed ability to promote centralized growth and property development in the heart of San Francisco than they were with reducing traffic congestion or air pollution. In spite of the public claims that BART would reduce local dependence on the automobile, there was no organized opposition to BART by the California highway lobby. In fact, at least one major oil company gave money for BART.

Los Angeles campaign of 1968. Six years after the successful BART campaign in northern California, Los Angeles attempted to build a similar rapid transit system. The Proposition A campaign of 1968 (Table 2) proposed to construct a combination rail and bus system that would be financed out of an increase in the local sales tax. The pattern of support was essentially the same as in San Francisco: large businesses near the central area of Los Angeles were the main source of organizational and financial support for the plan. Fourteen percent of the contributions came from heavy construction labor unions and from individuals, but approximately 86% came from business. Of

¹⁰ Contribution data for the BART campaign are incomplete. It was a regional election in the Bay Area and there was no official record of contributions required at that time. What information is available comes from a court deposition (by a chief pro-BART fund raiser) which resulted from a suit against organizers of the BART campaign. The deposition states that \$205,000 was raised in support of BART. Of the several contributors actually named, all were large corporations in the BAC.

this latter sum, industrial corporations gave 28.3%, insurance companies, 12.6%, oil companies, 10.9%, construction, engineering and architectural firms, 9.8%, and banks, 6.4%. This time a very small amount of money was contributed against the measure. It came from a car dealer, a rental agency, a public relations firm, an individual, and a cement company. In this case, the measure failed at the polls.

Proposition 18. The next important transportation issue to be decided by California voters was, unlike the two earlier ones, a statewide issue. Proposition 18 on the November 1970 California ballot proposed that up to 25% of the state highway trust fund, upon approval by voters in local areas, could be used to support public transit systems such as BART. The national and state highway trust funds are said to be jealously guarded by highway-auto interests (e.g., Kelley, 1971; Simmons, 1968) and this campaign was no exception. The California highway lobby¹¹ gave \$348,000 to successfully defeat Proposition 18 (Table 2). Leading contributors were: oil companies (75.1%), automobile clubs (12.9%), highway equipment and construction companies (7.9%), and trucking and taxi companies (1.8%).¹² On the other hand, virtually all of the small amount of money in support of Proposition 18 came from individual contributions. Only two California businesses, Kaiser Industries and Rohr Corporation, both with direct mass transit interests, gave small amounts for Proposition 18. The median contribution for Proposition 18 was \$5; the median contribution against was \$500. Although public transit systems like BART, and like the

system proposed for Los Angeles two years earlier, stood to benefit from the passage of the measure, the companies that had supported these systems in San Francisco and Los Angeles did not contribute for Proposition 18.

Proposition 5. Four years after Proposition 18 went down to defeat, a similar measure (Proposition 5 of 1974) was again presented to California voters. Proposition 5, somewhat milder than Proposition 18, permitted an initial 5% of the fund to be diverted should local voters so decide, with a maximum of 25% after a few years. This time there was almost a complete reversal of the pattern of business opposition that had been revealed in the Proposition 18 campaign (see Table 2). There was no public opposition to Proposition 5 by the highway lobby, and there was support for the measure by large businesses in urban centers (mostly Los Angeles). Contributions came mainly from one oil company¹³ (49%), from insurance companies (15%), other industries (6.5%), and banks (5%). This was in striking contrast to political positions only four years before. The measure passed this time.

Los Angeles campaign of 1974. The final campaign studied was Proposition A of 1974, another version of the unsuccessful Los Angeles campaign of 1968 to create a BART-like system. Again, there was a familiar pattern of support: central city businesses were the leaders in giving more than half a million dollars in support of the system (see Table 2). This time there was no money in opposition. As in the case of the earlier transit campaign in Los Angeles (1968), the Los Angeles electorate turned down the proposal: protransit money was not able to overcome Los Angeles voters' desire to avoid higher local taxes and presumably their pro-automobile attitudes. In each of the other three campaigns (BART, Proposition 18, and Proposition 5), however, the side that contributed the more money was successful.

¹¹ The list of companies contributing money against Proposition 18 matches closely the definition of the highway lobby by Kelley (1971), Simmons (1968), etc.

¹² These and all subsequent contribution data are from the records of the California Secretary of State. There is reason to believe that such records are generally accurate and complete. There are strict state laws requiring detailed reporting of contributions. Also, lists of contributors tend to conform well with interview data and with media accounts of campaign involvement. Nevertheless, these lists should be treated as *minimal* indices of contributions, since if a firm says it gave, it probably did: underreporting is more likely than overreporting.

¹³ The company was Atlantic Richfield, a firm which had recently opened the largest headquarters-office complex in downtown Los Angeles. ARCO's president was a leading organizer of the pro-Proposition 5 campaign.

Evaluation of Hypotheses

The goal now is to determine which of the three sets of hypotheses is supported most strongly by the data from these five political campaigns. Each of the sets of hypotheses will be discussed in turn.

Pluralist hypotheses. At the most simple level, these campaigns appear to provide partial support for the pluralist model. It can be argued that there was active involvement of several groups in these campaigns, groups with divergent interests that engaged in competition to affect public policy. For instance, the pattern of financial support exhibited in the five transit campaigns shows there are two relatively distinct interest groups (i.e., the highway lobby and the downtown transit interests) within the business world which compete to influence public transportation policy. Thus Table 1 shows that the transit interests supported the BART campaign, the two Los Angeles transit campaigns (Proposition A of 1968 and Proposition A of 1974), and the most recent successful attempt (Proposition 5 of 1974) to divert money from the highway trust fund to mass transit. The hand of the opposing highway interests was revealed in the intense campaign waged against the earlier unsuccessful try to divert trust fund monies (Proposition 18 of 1970). That interests and alliances have shifted over the course of the campaigns is indicated by the change in patterns of support between the Proposition 18 and Proposition 5 campaigns. The highway lobby opposed the earlier measure, but did not oppose the later similar Proposition 5. Moreover, while Proposition 18 received no support from downtown business, Proposition 5 got a great deal of support from these interests. It might be reasoned, therefore, that the successful passage of legislation (Proposition 5) to free some highway money for development of urban mass transit is a reflection of the growing power of nonhighway interests to countervail (cf. Galbraith, 1956) against the highway lobby and to force compromises. Political outcomes thus have moved away from almost exclusively favoring highway interests, demonstrating that political

power is pluralistic rather than monolithic.

While this is a plausible argument it does not dig deeply enough beneath the surface of events and tends to overlook some crucial aspects of these campaigns. These shortcomings are made clear when the next set of hypotheses is considered.

Power elite hypotheses. Most of the groups involved in the five campaigns were actually elite groups. With the exception of the organizers of the Proposition 18 campaign (i.e., the Tuberculosis and Respiratory Diseases Association of California, and the League of Women Voters) all of the campaigns studied were initiated, organized, and supported by business elites. Proposition 18 was the sole issue that did not appear to be a business production, and it lost. Thus, there was a high degree of business elite involvement and dominance in these campaigns.

An important issue is the extent to which elite interests converged on these issues (as the elite model would predict) or were divergent (which pluralist theory would predict). Here, the pattern is not as clear-cut as a simple competitive model would indicate. Interests are not the same as behavior. While there undoubtedly were some differences in interests (i.e., downtown businesses that desired new urban transit vs. suburban firms wanting additional circumferential highway development) the firms involved exhibited behaviors which were more noncompetitive than would be expected on the basis of the pluralist model. For example, in each of the five campaigns, business contributions fall into a pattern which is essentially noncompetitive: the money is virtually all on one side or the other of the issue. In spite of whatever conflicts of interest among the firms there may have been, there is no direct competition in terms of campaign money. This is especially clear in the case of the dramatic shift between Proposition 18 and Proposition 5. All business money was *against* Proposition 18 in 1970. Four years later, all business money was *for* the similar Proposition 5. This change was not, however, the result of individual companies switching sides. Those businesses

that opposed Proposition 18 dropped out of sight in the Proposition 5 campaign, while the supporters of Proposition 5 did not give for Proposition 18. Of the 52 firms that had contributed against Proposition 18, only one (i.e., the Automobile Club of Southern California) gave against Proposition 5; of 56 companies that supported Proposition 5, only two (i.e., Rohr and Kaiser, with trivial contributions) had given for Proposition 18. Thus there was a virtually complete reversal of business support for this policy (diversion of highway funds) and a 97.2% (105 of 108) turnover in the firms involved. Such a thoroughgoing change would appear unlikely to be caused by each company making a totally *independent* decision on this policy question.

Elitists might see this pattern as reflecting elite political coordination and unity. Clearly, this noncompetitive pattern does not fit the conventional pluralist model. However, some pluralists might attempt to counter by arguing that this pattern is merely a result of the understandable desire by companies to avoid overt (and costly) conflict. Lowi (1969:295), for example, has observed:

... Competition tends to last only until each group learns the goals of the few other groups. Each adjusts to the others. Real confrontation leads to a net loss for all rather than gain for any. Rather than countervailing power there will more than likely be accommodating power.

It is often in the interests of large businesses to avoid competition with each other, as in the case of the oligopolistic automobile industry (Snell, 1974; Rothschild, 1973). To such industries, lack of competition means operating under external conditions that are more predictable and which allow higher levels of profit.

Moreover, in an interdependent economy of mammoth economic units, many large firms must do business with each other (cf. Averitt, 1968). This mutual dependence can operate as a source of social control, preventing deviance beyond certain boundaries. For example, when a prominent San Francisco business executive and former head of the bond depart-

ment of Bank of America, was asked why San Francisco companies (like Bank of America) that had supported BART did not give money for Proposition 18, he replied:

... Standard Oil and the other oil companies are extremely important customers and they have a lot of clout in many ways. ... You take a banker, and Standard Oil, Union Oil, Shell—you name it—Mobil, Atlantic Richfield are good customers and if they say "We're opposed to this," it's awfully hard for the banker to say, "Well, we're in favor of it."

In order to resolve the issue of whether this noncompetitive pattern is indicative of positive elite coordination (elite model) or merely conflict-avoidance (a variant of the pluralist model) it is once again necessary to dig deeper.

Conflict-avoidance is an essentially passive strategy which requires little or no intralite communication or negotiation. On the other hand, elite coordination would require not only communication networks but also some means of settling differences and working out at least minimal joint plans of action. It is quite clear in the cases under investigation that communication and shared understanding did exist among the potential competitors. Almost without exception, business leaders speak of the "business community." As the former head of the Automobile Club of Southern California, current chairman of a conglomerate, and member of the exclusive Los Angeles Committee of 25, told me:

... I'm sure the business community is not the only group of people who consult with each other. ... It's a natural thing. So you kind of talk to the people you know and say, "What do you think about this?"

This "natural" process of communication, common to many self-identified groups in society, is especially consequential within the business community. As Schattschneider (1935:287) reminds us:

... businessmen collectively constitute the most class-conscious group in American society. As a class they are the most highly organized, more easily mobilized, have more facilities for communication, are more like-minded, and are more accustomed to stand

together in defense of their privileges than any other group.

A recent study by Moore (1977) has demonstrated the extent of elite cohesiveness in the United States. Using data from the American Leadership Study which are based on interviews with 545 leaders of major economic, political, and social institutions, Moore studied communication networks among these elites. The most significant finding for present purposes was that almost one-third of these leaders made up one enormous clique. Members discussed a broad spectrum of issues, resided in various parts of the country, and were generally quite heterogeneous in terms of institutional affiliations.

This evidence of elite cohesiveness would seem to provide a presumptive basis for interpreting noncompetitive patterns in terms of positive coordination. During the transportation campaigns it appears that in spite of initial differences among firms, extensive and rather effective attempts were made to overcome these diverse points-of-view and to achieve unity. As one of Los Angeles's leading businessmen, who had been very active in the transit campaigns in that city, told me:

Some of the people that opposed Proposition 18 also opposed Proposition 5. We couldn't get them to support it. I got into great arguments with some of my friends. In fact, I was president of the Chamber the year of Proposition 5. And I had the president of an oil company and the president of a railroad company opposing me on the fight, but I won the fight before the directors of the Chamber for our position. And when we won the fight both of those guys supported us. . . . When the thing was over with and 60 guys had voted, and there was only—I don't know—five or six votes on their side, they weren't going to fight the trend. . . .

And pointing out the importance to the business community of organizational membership as a mechanism for conflict-resolution and coordination, he added:

Between Proposition 18 and 5 we fought the thing out in the halls of the Legislature and in the Chambers of Commerce and the community organizations, in SCAG [Southern California Associated Governments] and all the rest of the places. . . . That's one of the reasons we belong to organizations like that.

This statement implies that conflicts within the business community over the use of a small portion of the California highway trust fund for rapid transit development were essentially resolved *within* the business community between Proposition 18 and Proposition 5. This could account for the lack of conflict in the *public* political arena: intrabusiness resolution obviates public resolution. The solution of this political conflict reflects the general tendency of the business community to seek consensus. As the former Bank of America executive pointed out in an interview, the pressure for consensus is strong. He used the analogy of the business community as a "club."

Well, if you belong to a club and the membership is up for a vote—if it's a secret ballot of course you don't know, but if there's any leakage that indicates that someone is opposed to someone, then you find that an awful lot of people follow the lead.

This club analogy is particularly appropriate in that, as Domhoff (1970; 1974) has shown, clubs and policy organizations are important in providing places for ironing out differences, discussing policies, and generating social solidarity among elites. A retired business executive, formerly a staff member of the California State Chamber of Commerce, and ex-head of the Western Oil and Gas Association, was asked about the role of face-to-face relationships in working out problems in the business community. He said:

Well, up on Nob Hill there's the Pacific Union Club. It's the most exclusive club in San Francisco and it's just across from the Fairmont and the Mark Hopkins [hotels]. All right, the leaders of San Francisco business go up there for lunch and maybe they have a big round table with twelve guys around the table, guys alone, otherwise they come in sometimes and they bring in guests, and they know each other on a first name basis and they [breaks off] . . . So they work together, partly on the basis of personal friendship, partly on the basis of devotion to the community, and I think they want to protect their own reputations as being cooperative.

This behind-the-scenes conflict-resolution and coordination is revealed more directly in a serendipitous event that occurred during another California politi-

cal campaign not examined in this study.¹⁴ Molotch and Lester (1974) point out the usefulness of studying accidents and scandals as a means of learning about political processes. In the Proposition 9 case, the scandal grew out of a memorandum from the office of the chairman of Standard Oil of California that was copied and given to the sponsors of Proposition 9 (the People's Lobby) by an employee of Standard. People's Lobby made the memo public and its contents were reported by the press. The memo was to the Standard Oil Chairman from a San Francisco lawyer and Sacramento oil lobbyist; the subject was the up-coming campaign over Proposition 9. The lobbyist suggested that a "citizens' committee" should be formed to "front" for the anti-9 forces rather than allow the function to be performed by the California Chamber of Commerce, the California Manufacturers' Association, or the Governor of California. The written comments on the memo (presumably those of the chairman of Standard) indicate approval of the plan. The document also suggests that a public relations firm (a firm well-known to Californians as often being in the employ of ultra-conservative politicians and political groups) be retained to manage the campaign. Attached to the memo was a preliminary campaign plan drawn up by that firm. Among other things it says:

In short, the campaign against the People's Lobby initiative must not be spearheaded publicly by business and industry. *It should be publicly launched by responsible conservationists, by academicians, labor spokesmen, leaders of the Democratic party, and joined at the appropriate time in the appropriate fashion by business, industry, agriculture, and the Republican party leadership.* (emphasis in original)

¹⁴ The People's Lobby, a California public interest group, succeeded in gathering enough signatures to qualify an initiative for the June 1972 California ballot. The complex measure (Proposition 9 of 1972) was oriented toward environmental reform. Its provisions included the phasing out of leaded gasoline, closer monitoring of polluting industries, the banning of offshore oil drilling, a five-year moratorium on new nuclear power plant construction, and the banning of persistent chlorinated hydrocarbons such as DDT. Thus, it was reasonable to expect strong opposition from heavy industry, especially oil and utility companies.

The plan also made clear who would actually be running the campaign—the oil and utility companies of the state:

The involvement of the principal oil companies and the principal utilities . . . *is not a public involvement.* Rather, in a non-publicized sense, it is a means of directing the campaign under the aegis of a *public* citizens committee as outlined. In the doing, total control of the public campaign strategy and direction is maintained. (emphasis in the original)

This "total control" would be achieved by "a small steering committee which would not become public, composed of the delegated spokesmen for the principal utilities and oil companies." As a front, it would be necessary to create a "public citizens' committee" that would be "expanded obviously right up to election day." The public structure was needed in order to avoid "a big business versus people's issues which can only be self-defeating."

The important thing about this memo is not that it reveals a Machiavellian attitude toward the political process. The existence of such attitudes will come as a surprise to few of us. What is important about this memo is that the whole tone of the document *takes for granted* that *total control* of a campaign by big business is entirely *possible*, and does not consider problematic the concurrence of other oil and utility companies, business and industry, the California Chamber of Commerce, the California Manufacturers Association, or even the Governor of the State.

A strong indication of political coordination by business elites emerges from data relating to the transit campaigns studied herein. The pattern of contributions against Proposition 18 and for Proposition 5 provides evidence of a high degree of organization and coordination, suggesting some sort of assessment system based on the value of assets or on sales volume. Table 3 shows the relationship between the amount of gasoline sold by the largest companies in California (including two that did not donate) and the size of their contributions against Proposition 18. It is doubtful that such a strong relationship, in which nearly 90% of the variance is accounted for, would hold in campaigns which are truly spontaneous

Table 3. Oil Company Contributions against Proposition 18 by Amount of Gasoline Sold in California

Company	Gas Sold (1969) ^a (x)	Contribution (y)
1. Standard of Calif.	1,642 million gallons	\$75,000
2. Shell	1,497 million gallons	\$50,000
3. Union	876 million gallons	\$20,000
4. ARCO	824 million gallons	—
5. Mobil	810 million gallons	\$30,000
6. Texaco	689 million gallons	\$20,000
7. Phillips	415 million gallons	\$15,000
8. Gulf	410 million gallons	\$20,000
9. Humble	320 million gallons	\$20,000
10. Signal	242 million gallons	—
11. Douglas	192 million gallons	\$5,000
$r^2 = .76$		
$r^2 = .89$ when ARCO and Signal are deleted.		

^a Source: 1969 gasoline sales figures from California Board of Equalization.

and uncoordinated (and where each does not know the amounts given by others).

An even stronger relationship, a nearly perfect one, is found in the case of bank contributions for Proposition 5. Table 4 shows the total assets of the largest eight banks in the state (all of whom gave) and the amounts contributed. In this case, bank assets entirely account for size of contribution. And even though each contribution is for an unusual amount (e.g., \$1,070), the total for the largest banks is an even \$10,000, suggesting that an overall quota was set for this group with smaller banks assessed on a proportionate basis.¹⁵

This evidence of elite attempts to achieve unity, to coordinate strategies, and even to control political processes behind the scenes is clearly more supportive of the power elite model than the pluralist model. Yet, an even greater understand-

ing of these campaigns can be attained by a consideration of the class-dialectic model. Again, we must dig deeper.

The Class-Dialectic Hypotheses

The class-dialectic model stresses the importance of looking beyond the immediate political events under investigation in order to understand the historical and institutional context within which they take place and by which they are shaped. At the extreme, to focus merely on proximate behavior of individuals and groups without seeking to discover how this behavior articulates with institutional imperatives in the larger society is analogous to trying to understand the behavior of people in a classroom setting without knowing that grading systems, ability testing programs, academic diplomas, social status indicators, and educational requirements for jobs exist.

The influence of social institutions and their biases has been commented upon by Lukes (1974:21-2) who writes:

Decisions are choices consciously and intentionally made by individuals between alternatives, whereas the bias of the system can be mobilized, recreated and reinforced in ways that are neither consciously chosen nor the intended result of particular individual's choices. . . . Moreover, the bias of the system is not sustained simply by a series of individually chosen acts, but also most importantly, by the socially structured and culturally patterned behavior of groups and practices of institutions, which may indeed be manifested by *individuals' inaction*. (emphasis added)

¹⁵ Seemingly, some means had been used to coordinate these two sets of contributions. Interviews uncovered the answer. In this case of the oil companies, the Western Oil and Gas Association (WOGA) was the agent for coordination. The General Manager of WOGA calculated the "fair share" of oil contributions based on "gallons" of gasoline sold in California. He then told the companies what amounts would be appropriate, "if they were going to give." This prorating of contributions by WOGA has been going on at least since the 1940s, according to a former WOGA general manager.

The same function was performed for the banks by their clearing house (formally organized to settle accounts between banks, as by exchanging checks drawn on other member banks, etc.). An executive of Wells Fargo Bank told me that it has long been a practice for the banks' clearing house to decide how much to give on an issue, with the banks then contributing "in relation to their size."

Table 4. Bank Contributions for Proposition 5 by Total Assets

Bank	Assets* (x)	Contribution (y)
1. Bank of America (SF)	\$49.0 billion	\$4,210
2. Security Pacific (LA)	13.4 billion	1,610
3. Wells Fargo (SF)	11.6 billion	1,280
4. Crocker National (SF)	9.5 billion	1,070
5. United California	9.0 billion	920
6. Union Bank (LA)	4.8 billion	410
7. Bank of California (SF)	3.0 billion	290
8. First Western (LA)	1.4 billion	210
		\$10,000
$r^2 = .98$

Lukes criticizes most studies of power as being too "behavioral," thus not sufficiently attuned to the influence of the bias of social institutions. It is the bias of political, economic, and cultural systems that partly determines what we will see as political problems and opportunities, what are likely to be admitted to the agenda as formal issues (cf. Bachrach and Baratz, 1962) and what will seem to us as politically possible or impossible. In some cases, such as those analyzed by Weinstein (1968) and Domhoff (1970), certain groups—particularly dominant classes¹⁶—are able to make their own imprint on the institutions of the day. It is this relation between political processes and social institutions that the class-dialectic model aims to explicate.

Let us apply this perspective to the cases under study here. This requires, of course, that we look at a larger context than was true in the case of the pluralist and elite models. This difference in inclusiveness is a central factor separating the class-dialectic model from the other two.

Our society has a market economy in which most major decisions concerning the production of material goods and services, investments to be undertaken, and levels of profit to be obtained are in the hands of private groups and individuals. In contrast to more planned economies, problems of coordination and overall societal rationality result. Certain contradictions are built-in.

The case of transportation in the U.S. is

illustrative. There is a contradictory aspect to transportation in that it is treated primarily as a private good rather than a public service. The nation is overwhelmingly dependent on the private automobile for getting around, yet this very dependence has created the familiar problems of traffic congestion, excessive use of energy, air pollution, thousands of deaths and injuries each year, the necessity for enormous sums of money to be spent on streets and highways, and has exacerbated the trends toward suburbanization and central city decline. Although the production of private automobiles and related goods (e.g., oil and gasoline, tires, steel) is at the heart of the economy, we have paid high social costs (Mowbray, 1969; Kapp, 1971) and have been subjected to social irrationalities of a serious nature (Downs, 1970; Mumford, 1963; Snell, 1974). There is a contradiction between the ardent promotion and selling of automobiles as apparent individual solutions to transportation needs (which from the lone consumer's viewpoint may appear efficient and desirable) and societal needs for rational, planned, peaceful cities, and efficient and equitable public transportation. Because the private economy looks upon transportation primarily as an opportunity for profits, socially irrational and contradictory developments arise. For example, during the time that the initial plans were being laid for BART in the San Francisco Bay Area, the then-existing electric trolley lines were being dismantled by a consortium of automobile and bus interests (Zwerling, 1974; Barnes, 1973:18). During the 1930s, and 1940s, and 1950s, similar events were taking place in

¹⁶ The empirical usefulness of Marxist class categories has recently been demonstrated by Wright and Perrone (1977).

more than 45 cities around the country (Snell:1974:). These rational, efficient systems (cf. Crump, 1962) were destroyed primarily because a profit could be made in so doing.¹⁷ Now when it is recognized that there is a need for such systems in our cities, new systems like BART are not only prohibitively expensive, but also are not designed to accomplish the same purpose.

As pointed out earlier, a good part of the motivation of the firms that supported the construction of BART in San Francisco and similar systems in Los Angeles had not so much to do with social rationality as with profit. Molotch (1976) has shown how cities can be seen as economic "growth machines" in which property holders, businesses and politicians tend to single-mindedly promote population and economic growth as a means of enhancing land values and sales. The expectation among Bay Area Council member firms of increased central city growth appear to have been of great importance in the case of BART (Whitt, 1975). The system has been heavily criticised as not providing adequately for the general transit needs of Bay Area residents, particularly those who are most in need. BART represents a contradiction because it was developed primarily to augment the private profits of San Francisco's major businesses and not to effectively deal with the many problems created by the untrammelled development of the profitable private automobile.

Such piecemeal attempts to deal with contradictions also are increasingly running afoul of another contradiction in the society. O'Connor (1973) has demonstrated how the current budget difficulties of state and local governments can be traced to structural contradictions in the economy. Large firms such as those that supported BART favor creating new

transit systems, but of course have no intention of paying the entire cost for the construction of these very expensive systems. Government is a logical source of funds. However, the federal government is increasingly hard-pressed due to the budget crisis and has become more reluctant to fund large and costly BART-like projects. The solution attempted has been to try to get local citizens to pay an increasing share through sales taxes (as in the two Los Angeles cases) or property taxes (as in San Francisco), both kinds of taxes being generally recognized as regressive. Not surprisingly, there often has been voter resistance of the kind that defeated the two Los Angeles plans.

This need, from the standpoint of dominant classes, for a certain level of acquiescence on the part of subordinate classes leads to the institution of various methods aimed at attaining social control, mass persuasion (cf. Schiller, 1969), and the maintenance of the legitimacy (Miliband, 1969) of present institutional structures upon which class hegemony is based. But as O'Connor (1973) has demonstrated, the maintenance of class-based institutions may be contradictory to the maintenance of legitimacy.¹⁸ Therefore, inherent contradictions and the awareness of benefits or costs which are differentiated by class may place limits on possible actions by the dominant class. For example, the awareness by urban dwellers that they will be paying for new, expensive urban transit systems which they often feel will benefit others more than themselves sometimes leads to the rejection of the planned systems. In short, mass persuasion does not always work, just as structural contradictions cannot always be overcome.

In contrast to the elite model, dominant classes do not always win each battle.

¹⁷ Snell (1974:30-1) indicates how National City Lines and other companies organized by General Motors, Standard Oil of California, and Firestone Tires bought up existing electric streetcar companies, tore up the tracks, and replaced the streetcars with buses. Then converted systems would be resold to local concerns with the agreement that only GM buses, fuel produced by Standard Oil, and Firestone tires be used in the new systems. The conversion of over 100 systems produced large and continuing profits.

¹⁸ In their excellent elaboration and refinement of O'Connor's perspective, Friedland et al. (1978) argue that the contradiction between accumulation and legitimation may not be inherent and continuous. For example, they point out that:

Much of the time, perhaps most of the time, a stable and prosperous economy is also a precondition of the legitimacy of the state, for the breakdown of the accumulation process leads to the loss of jobs, declining real income, and the series of dislocations which give rise to political discontent. (1978:220)

There are also *intra*class differences and conflicts which must be dealt with. Many potential and actual conflicts emerged during the transit campaigns. Not all business executives were equally enthusiastic about new transit systems, but, even more clearly, they were not agreed about whether the *highway fund* should be used to pay for new systems. Hence the extensive behind-the-scenes conflicts and negotiations over the merits of Proposition 18 and Proposition 5, both of which proposed to tap in minor ways the state highway trust fund. In this case the business class was able to pull together and achieve at least a degree of unity and coordination on this potentially divisive issue. Apparently, there was great motivation to strive for class unity. As one business executive told me, businessmen "... want to get along as a community ... and they don't want to go off in different directions." As in the elite model, there is emphasis here on attaining unity, but the class-dialectic model holds that, due to class conflicts and contradictions, unity is not always possible. Also, the latter model points to the seeking of legitimacy as a further restriction on the actions of the dominant class. For example, the search for legitimacy is revealed in the Standard Oil memorandum which was quoted earlier. At one point, the memo warns that it is necessary to set up a public committee to "front" the campaign for the "utilities and the oil industry" in order to avoid creating a "big business versus people's issue which can only be self-defeating."

Contradictions and conflicts are never static. As Chambliss (1979) compellingly argues, the "solution" of one contradiction often leads to the emergence of others. This is the essence of the dialectical conception of history and political power. For example, the introduction, mass production, and intensive promotion of the private automobile (cf. Flink, 1970; 1975), produced, in the words of Baran and Sweezy (1966:219-20):

... a radical alteration of economic geography with attendant internal migrations and the building of whole new communities; each [i.e., the steam engine, the railroad, and the automobile] required or made possible the production of many new goods and services;

each directly or indirectly enlarged the market for a whole range of industrial products.

This was very profitable for American industry and provided a base for many large fortunes and the growth of privileges in certain segments of the dominant class (Carnegie in steel, Ford in autos, Rockefeller in oil, etc.). But in recent years the possibilities in these auto-related areas have begun to dim. Rothschild (1973) argues that the auto industry is now in a state of stagnation and decline. Contradictions and social costs of automobile production and use have become manifest. The decline of this and related industries, the energy crisis, the loss of viability of central cities (particularly in the Northeast), the challenge of foreign competition, and the demands of people for better public transportation have all forced a readjustment and response by the dominant class. The former "solution" of vast industrial expansion, healthy profits, and increased class privilege which attended the rise of the private automobile has revealed other contradictions. No solution lasts forever. Now something must be done to "save" the valuable central city as a producer of profit, and to ease some of the most damaging impacts of the automobile. Such systems as BART are supported by dominant business classes as a way out. That they do not really work so well and are very costly is now being realized. Another series of contradictions awaits.

It is this broader context which allows us to more fully appreciate the political events herein analyzed. Now we see more of the motivation behind such campaigns, the contradictions and conflicts manifested therein, and the reasons for the previously difficult-to-explain pattern of political contributions. We can see these political events in the context of the contradictions which the dominant class must face: (1) the market economy vs. the need for some planning, (2) the selling of transportation as a private good vs. the requirement for public services, (3) the competition among cities and among capitalists for growth-generating developments vs. coherent structure and regularity in urban development, (4) the need to construct new urban transit systems vs.

the budget crisis and occasional mass resistance, (5) the desire for class hegemony vs. the requirements of legitimacy and mass persuasion, and (6) the desire for class unity vs. the divisive tendencies of intracapitalist class differences and conflicts. I would argue that an appreciation of these six factors, to which the class-dialectic model sensitizes us, adds much to our understanding of the political events analyzed here. Rather than seeing these events as simply the clash of organized interest groups pursuing their own goals as the pluralist model would hold, or as the reflection of an elite working its will, we see that the situation is more complex than either of these models would lead us to believe. There is both competition and cohesion here, but that is not the real point. It is most important to understand that the capitalist class must respond to contradictions and crises in the economy, in the cities, and in the polity. Continued class hegemony and the legitimacy of present social institutions require class-based action. Yet, those actions must contend with numerous contradictions. New ones arise as old ones are vanquished. The coming of the automobile solved certain problems but created others. These transit campaigns upon which this paper has focused were rather ineffectual attempts to deal in a small and local way with some of the more glaring aspects of these contradictions. That actions appeared somewhat contradictory, based on a strange mixture of cooperation and conflict is not surprising.

In conclusion, the following points should be made. It is possible to analyze political processes on several levels. As the class-dialectic model uses the most general level of the three models, various aspects of the pluralist and elite models are not incompatible with the former. The pluralist model is fairly accurate as far as it goes, but as I have tried to show here, it does not go nearly far enough. The elite model is more adequate in that it does begin to more fully appreciate the institutional influences that shape political behavior. But it too does not go far enough because it does not envisage the complexity of the structural contradictions to which the dominant class must respond

and does not recognize the inherent dialectical nature of power.

This paper has attempted to suggest the empirical usefulness of the class-dialectic model of political power, a model which has not been taken seriously at the community level of analysis. I maintain that an empirical and theoretical elaboration of this perspective can help us to get beyond the longstanding pluralist/elitist controversy and can sharpen our understanding of politics at the local level as well as the national and international. It is time for an integration of the various levels of analysis. The class-dialectic model can give us that integration.

PARADIGMS IN EVOLUTIONARY THEORY: THE SOCIOBIOLOGICAL MODEL OF NATURAL SELECTION*

JILL S. QUADAGNO

University of Kansas

American Sociological Review 1979, Vol. 44 (February):100-109

One of the few theories in the history of ideas which has been held in common by both the social and natural sciences as well as philosophy is that of evolution. As a scientific paradigm evolutionary theory can be analyzed according to five principles: change, order, direction, progress and perfectibility. Darwinian evolutionary theory was based on the idea that change in forms occurs through the mechanism of natural selection. Darwin's central problem was to explain the apparent instability of species, which he observed in fossils. In contrast, the central problem of sociobiology has been to explain the evolution of social behaviors, including complex human social behaviors. A key issue has been the origin of altruism. In explaining the origins of social behavior, sociobiologists have altered the paradigm of evolutionary theory as originally formulated by Darwin in several ways. First, they have argued that the principal effect of natural selection must be the maximization of reproduction. Second, the concept of fitness has been altered; species typical behavior has come to be defined as fit behavior. Third, there has been an increased stress on the adaptive nature of behavior, with the subsequent effect that nonadaptive evolution has been ignored. Two specific examples of sociobiological reasoning which both purport to explain altruism, kin selection and reciprocal altruism, provide an example of tautological reasoning. In terms of both logic and method, sociobiology cannot be applied to the analysis of complex human social behavior: Sociobiology is based on a preconceived notion of change leading to a necessarily adaptive order in which the morality of human consciousness is replaced by the morality of gene survival.

Until recently evolutionary theory was reserved for the analysis of forms, while human social behavior remained largely within the domain of the social sciences. Sociobiology is application of the laws of natural selection to social behavior, including human social behavior. Sociobiological theory states that genes provide the information that structures social behavior.

Sociobiologists, issuing a challenge to social scientists, claim that we will eventually be subsumed or, in the words of E. O. Wilson (1975:4), "biologized" by this developing discipline. Most of the responses thus far from social scientists (as well as others in danger of being subsumed) have taken one of two critical

forms, either sociopolitical or scientific. This paper will not address its critique to either of those two levels of criticism directly, although flaws in the methods of sociobiology will be discussed. Rather the scope of the analysis will be broadened by examining sociobiology as a set of philosophical principles which organize the world in a particular way. Attention will first be directed toward an analysis of the principles of evolution as a general world view. Then the Darwinian formulation of organic evolution will be presented. Finally, the interpretation of evolutionary theory which characterizes sociobiological thought will be critically assessed. Throughout, the usefulness of applying evolutionary theory to complex human social behavior will be questioned.

THE PARADIGM OF EVOLUTIONARY THEORY

Thomas Kuhn's influential book *The Structure of Scientific Revolutions* introduced an awareness that much of what we accept as "truth" in science is, in fact, a reflection of an acceptable world view,

induced by anomalies in previous systems, made palatable due to compatibility with political and economic belief systems. Each paradigm tells us "different things about the population of the universe and about that population's behavior" (Kuhn, 1970:103). Scientific theories, as they evolve, represent shifts in vision, perceptual transformations, in which "scientists see new and different things when looking with familiar instruments in places they have looked before" (Kuhn, 1970:111). As a paradigm each theoretical system tells scientists which problems to study and how to study them.

One of the few theoretical systems in the history of ideas which has been held in common by both the social and the natural sciences as well as philosophy is that of evolution. Evolution is a world view which embodies many principles, not all of which are admitted in its various uses. Even those concerned with organic evolution, which is its most commonly known form, are unable to agree on the essence of evolution (Lewontin, 1968:202). In the evolutionary world view as a general paradigm, a hierarchy of principles can be identified. These include change, order, direction, progress and perfectibility, with each principle being present in some but not all theories of evolution.

The idea of evolution in its simplest form envisions a system in a continual state of change. This is opposed to a nonevolutionary world view in which change occurs as a result of special intervention of unique forces in an otherwise static system. To this, in many evolutionary schemes, is added the principle of order, that is, a change from one order to a different order. The fact of order is based on a preconception. We cannot know order from chaos unless we have some preconceived idea of how order can be recognized. As Lewontin (1968:203) states:

The demand that an evolutionary process create order or at least that there be a change from one order to a different order, shows clearly that evolution, in this sense, is neither a fact nor a theory, but a way of organizing knowledge.

Direction as a principle in evolution re-

fers to some natural linear order which can be described on an ascending or descending line. Evolutionary theories which incorporate direction must be able to construct a system in which there is a tendency to increase or decrease. For instance, human cultures have been ordered in a linear direction based on modes of organization from hunting and gathering to agriculture, from agriculture to industry (Lewontin, 1968:204). The scale has varied, based on, for example, the degree of the division of labor (Durkheim) or degree of complexity (Spencer). In either case, a recognizable linear order has been devised.

Evolutionary theories which include a moral tone in their description of direction can be said to incorporate the principle of progress as well. The idea of progress refers to more than just change from, say, simplicity to complexity, for there is included some sense that complexity is better. Finally, in a few evolutionary theories the notion of perfectibility in the system is included. The inclusion of this utopian element is rare, for most evolutionary processes are envisaged as having no particular perfect end goal.

THE DARWINIAN MODEL OF EVOLUTION

When Darwin introduced his theory of organic evolution by means of natural selection to the scientific community in 1859 with the publication of *The Origin of Species*, the concept of evolutionary change had already been present in philosophy and the natural sciences. By extending it to organic matter, the evolution of forms of species, Darwin touched on the origins of human beings and challenged their preordained supremacy in the universe. In this sense, Darwinian theory represented a major paradigm shift over earlier theories of organic evolution. Pre-Darwinian evolutionary theories such as those espoused by Lamarck, Chambers, Spencer and the German *Naturphilosophen* had taken evolution to be a goal-directed process, incorporating the principles of direction, progress and perfectibility. The "idea of man" was believed to have been present from the first

creation of life and that idea provided the direction to the entire evolutionary process (Kuhn, 1970:172). In *The Origin of Species*, Darwin recognized no goal set by God or nature; through the mechanism of natural selection, continual change led to an unpredictable new order.

The Darwinian formulation predicts that change will occur and will continue to occur, but it does not predict the content of that change (Couch, 1978:24). Forms change in response to changes in the environment, producing new forms. This change is not predictable, because environmental changes are not predictable. The mechanism of change which leads to new forms is natural selection. Natural selection was a simple concept implying that differential survival led to differential reproduction.¹ In this sense, it was a minimal principle. Selection becomes positive the moment any relative advantage is produced (Sahlins, 1977:75). Species adapt to ecological niches in the environment and obtain a positive advantage over conspecifics by producing more offspring that survive based on prevailing environmental circumstances. In Darwin, order as a principle is subsumed under the principle of change. Organic evolution is a change in the genetic composition of populations. Thus, order merely is implied in the taxonomic comparison of forms and has no independent ontological status as in movement out of chaos.

While there is an identifiable linearity in Darwin's view of evolution, it is branched rather than being merely linear and has no *necessary* direction. In general, organic evolution proceeds from simplicity to complexity; organisms evolve from less complex to more complex forms. However, overall movement toward greater complexity is not an inherent part of the Darwinian paradigm (Couch, 1978:29). In fact, Darwin recognized that changes from complex to more simple structures occurred, even though evolution was more likely to proceed in the other direction. Darwin (1859:171, 340, 443, 456) essentially considered evolution to be any

hereditary change occurring within species over time (descent with modification), regardless of the direction of change.

In contrast to earlier theories, Darwin clearly and specifically rejected progress and, by implication, perfectibility as principles inherent in evolutionary change (Freeman, 1974:218). Numerous statements written as early as 1844 can be found to support this contention. In a letter to the American zoologist, Alpheus Hyatt, at the end of 1872, Darwin concluded, "After long reflection I cannot avoid the conviction that no innate tendency to progressive development exists . . ." (cited in Freeman, 1974:218). In another letter to J. D. Hooker he wrote, "Heaven forbid me from Lamarck nonsense of a 'tendency to progression' . . ." (Freeman, 1974:213). If there was any conception of progress present, it was progress for any group of organisms toward better adaptation to ways of life available for that group. Progress for a crab was not to become more human, but to become a better crab (Simpson, 1974:229). Darwin has been misunderstood on this point by some due to his use of the term *survival of the fittest* which could be read to imply progress. It should be recalled that this term was coined by Spencer (1864) and was not adopted by Darwin until the fifth edition of *Origin of Species*. Spencer, criticizing the term *natural selection* as unnecessarily personifying nature, preferred *survival of the fittest* as a plain expression of fact. Darwin eventually acknowledged the validity of Spencer's argument and incorporated the phrase into his text (Merchant, 1916:174-5).

Thus, the original formulation of evolutionary theory by Darwin saw randomly occurring continual change in nature leading to a new order of forms fitting ecological niches in the environment. While there is an implied linearity in the ordering of species, no extrapolation was made regarding the movement of species in either direction on that linear scale. Process was only perceived as better adaptation. Since neither individual nor environmental conditions are predictable, the hallmark of

¹ The term *natural selection* was used in contrast to artificial selection.

Darwinian evolutionary change was indeterminacy.

THE SOCIOBIOLOGICAL MODEL OF NATURAL SELECTION

The view that evolutionary theory is a paradigm within the biological sciences representing a particular world view is not, of course, a statement of fact, but a perspective, which can be accepted or rejected, depending on how one prefers to view the nature of science. Sociobiologists, as well as other evolutionary theorists, often prefer to see scientific knowledge as accumulated facts. For example, Barash (1977:9), rejecting the basis of scientific inquiry as paradigmatic, states that evolutionary theory is "not just a theory; it is probably as close to truth as we can get in natural science." Along with Wilson, Alexander and other sociobiologists, Barash has accepted a set of assumptions regarding the meaning and status of evolutionary theory. As we shall see later, this determines not only which questions are asked but also influences how they are to be answered, placing limitations on the potentially vast array of conclusions available.

Darwin's theory of natural selection arose from his observations of variations of forms of fossil animals as they occurred in slight succession on each of the islands of the Galapagos archipelago (Barlow, 1958:118-9). During his naturalistic observations, he noted the apparent instability of species, which led to his eventual conclusion that species were not fixed and intransitive but evolved.² Darwin's central problem was to explain this instability; in contrast, the central theoretical problem of sociobiology has been to explain altruism (Wilson, 1975:3).

Altruism and the Development of Sociobiology

The problem initially arose from a debate between group selectionists and indi-

vidual selectionists who were attempting to explain the evolution of altruism. Altruism has been defined by sociobiologists in the following way: "When a person (or animal) increases the fitness of another at the expense of his own fitness, he can be said to have performed an act of altruism" (Wilson, 1975:117). This brought up the rather sticky dilemma of explaining how a behavior which by definition reduces personal fitness could possibly evolve by natural selection. After observing many instances of animal behavior which appeared to be altruistic, thus reducing an individual's likelihood of reproductive success, scientists were perplexed about how the quality of altruism could ever be selected for in any given species. In the early sixties Wynne-Edwards (1962) published his now discounted *good of the species* or group selection argument. The essence of his argument, which is not central to this essay, was that individual animals exercised reproductive restraint to protect the species from disastrous population crashes which would follow unrestrained growth and the exhaustion of resources.

In refuting Wynne-Edwards's thesis and finding alternative explanations for altruistic behavior, certain changes were made in the underlying logic of evolutionary theory. First, in refuting the notion of reproductive *restraint*, evolutionists (and with increasing emphasis sociobiologists) argued that the principal effect of natural selection must be the *maximization* of reproduction. While this can take many different appearances not always coincident, to the outside observer, with a mad scramble to reproduce, it is the ultimate goal. Thus, selection was transformed from a minimum principle, becoming positive when any relative advantage in breeding is produced, to a maximizing one.

This preoccupation with maximization can be readily documented in the writings of a variety of sociobiologists. Williams (1966:132) writes, "[T]he reproduction of every individual is designed to maximize the number of its successful offspring." In speaking of maximum net returns, Trivers (1972:139) states:

For a given reproductive season one can define the total parental investment of an indi-

² The noticeable similarity in structure between species which performed similar functions also served as an impetus for the development of evolutionary theory.

vidual as the sum of its investments in each of its offspring produced during that season, and one assumes that natural selection has favored the parental investment that leads to maximum net reproductive success.

Similarly, according to Alexander (1975:90), "all organisms are assumed to be evolving continually to maximize their own inclusive fitness."

The second change in the Darwinian concept of evolution that occurred as a response to the group selection argument was an alteration in the meaning of fitness. Sociobiologists expanded the concept to mean more than just a reproductive advantage; species-typical behavior came to be defined as fit behavior³ (Alexander, 1975; Wilson, 1975:67). Fit behaviors are selected for, while nonfit behaviors are selected against. Thus, if a given behavior is exhibited by a species and typical of that species, it must be fit. There is an obvious tautology to this argument that was not present in the original concept of fitness. Wilson himself warns against the danger of tautological reasoning in his discussion of the Fallacy of Affirming the Consequent. He states:

In scientific practice the fallacy takes the form of constructing a particular model from a set of postulates, obtaining a result, noting that approximately the predicted result does exist in nature, and concluding thereby that the postulates are true. The difficulty is that a second set of postulates, inspiring a different model, can often lead to the same result. (Wilson, 1975:29)

In spite of the fact that Wilson is aware of the potential problem in sociobiological reasoning, this circularity becomes inevitable, particularly when applied to human social behavior. An example of this inevitability will be documented in detail later.

The third transformation in evolutionary theory occurred in regard to the concept of adaptiveness, which is conceptually linked to fitness. Sociobiologists who are concerned with the adaptive significance of animal behavior define an adaptation as "any evolved characteristic of an organism that increases its fitness"

(Barash, 1977:33). Thus, any trait which increases the fitness of an organism is adaptive. In and of itself, this is not problematic, but sociobiologists assume that behavior patterns *are* adaptive (Barash, 1977:33). If they exist, it is because they have conferred some selective advantage, thus increasing the adaptive fitness of the organism. This is basically another way of saying that species typical behaviors are fit behaviors, because they are present. This argument contains the same tautological reasoning.

Aside from the tautological reasoning introduced into the process of evolution, this concern with adaptive fitness has led sociobiologists to conceptually exclude other mechanisms that lead to evolutionary change. Most evolutionary theorists have come to recognize that evolutionary change is not a simple matter of selection but a complex combination of mechanisms including migration between gene pools, recombination and genetic drift. No single mechanism accounts for all evolutionary change, although natural selection is regarded as the most general determinant. In other words, natural selection as a response to changes in environmental conditions is one aspect in a series of factors which influence evolutionary change, and many differences between groups can be attributed to *nonadaptive* differentiation (Dobzhansky, 1937; Dobzhansky and Pavlovsky, 1967; Lewontin, 1974; Wright, 1967).

There is no doubt that sociobiologists, who are after all serious scientists, are aware of other mechanisms of evolutionary change. Wilson devotes a portion of one chapter to an explanation of other evolutionary forces such as genetic drift, mutation and recombination, yet he and others choose to conceptually ignore the possible effects of nonadaptive differentiation (Wilson, 1975:65; Barash, 1977:33). As Barash (1977:33) emphasizes:

A fundamental assumption of sociobiology is that behavior patterns are in fact adaptive. Indeed, this is the basis for our present concern with natural selection and evolutionary process. However, some debate currently exists among evolutionary biologists as to the extent of adaptive versus nonadaptive

³ Actually sociobiology extended a trend that had begun with earlier additions to evolutionary theory.

(random) factors in evolutionary change. Most opinion favors the former, and this book will be concerned with behavior as an evolved adaptation of living things.

The issue is not so much what proportion of evolution can be explained by adaptive as opposed to nonadaptive factors, but rather how this singular emphasis has transformed the evolutionary paradigm. The concern with the maximization of adaptive fitness which is then used to explain presently existing behaviors distorts both evolution and the actual state of affairs in the real world. Sociobiologists tend to describe things as if they were one hundred percent adaptive, having maximized their reproductive fitness because they exist (Daly and Wilson, 1978; Trivers, 1972:139). Even though they are aware that evolution need not produce maximal solutions, they tend to forget or simply ignore the fact that this is the case. In reality the evolutionary process can only be defined and comprehended relative to a given set of environmental and demographic circumstances. Factors such as nutrition, toxins, accidents and learning experiences introduce phenotypic variance that is beyond the control of the genotype, often reducing the adaptiveness of the organism. Thus, maximization can never really occur and even if it did, it would be impossible to identify it. Conversely, making the assumption that behaviors which presently exist represent the maximal adaptiveness of the organism makes it impossible to find behaviors which are not maximally adapted; by definition they cannot exist.

This may appear to be an oversimplification of the underlying logic of sociobiological theory. In a sense, it is, since there are valid studies applying sociobiological concepts to some simple forms of nonhuman behavior. However, the methodology of sociobiology in the study of simple, nonhuman behaviors does not require the same kind of logical leap to relate theory to empirical fact that it does in understanding complex human behavior. In order to explain this more fully, it is first necessary to recall that the main method of evolutionary theory when

applied to forms is an historical approach⁴ (Lewontin, 1968; Sahlin, 1977). As history it is made up of existential statements rather than universal ones that are falsifiable according to Popper's criterion. As Lewontin (1968:207) explains:

The evidence that evolution has in fact occurred is contained in the succession of fossils found in different geological strata. From the fossil record we can state with confidence that there are many kinds of animals and plants that, having once existed, no longer exist. But that statement itself, far from being a universal statement, is an existential one; in fact it is a historical statement, exactly corresponding to the assertion that Napoleon once lived or that Martin Luther died on February 18, 1546, at Eisleben.

This interpretation of history, as the reconstruction of archeological remains, is a narrow one, admittedly excluding socially constructed meanings. As such it provides a reasonable perspective for providing an explanation, not in the sense of predictive power, but "understanding" as an account of remains.

Obviously when analyzing the history of behavior, there are no fossil remnants to provide clues around which to reconstruct historical movement. Instead history must be reinterpreted to signify comparisons between closely related species in order to identify phylogenetic sequences (Barash, 1977:53; Wilson, 1975:550). Even in analyzing simple, nonhuman behaviors, this method has a major weakness. As Barash (1977:53) admits, "In most cases, the proposed phylogenetic sequences seem eminently reasonable, but in the absence of fossil behavior patterns there is no definite way to refute or verify the assumption of which behavior came first." If verification is a problem in the analysis of the ultimate causality of simple, nonhuman behavior patterns, then consider the consequences in attempting to use the same method for complex human behaviors. Humans would have to be compared with other

⁴ There are other methods proposed by sociobiologists, including evaluative, correlational and predictive. Similar flaws can be demonstrated in these methods but for the sake of brevity, this task will not be undertaken in this paper.

primate species. However, other primate species do not have culture, so the comparison at best could only deal with very basic behavioral traits. Further, as Wilson admits, this method cannot be applied with confidence in humans. In addition the same problem of verification holds true, as it does for all sociobiology.⁵

Applying the Theory of Sociobiology

To prove that this description of the method and logic of sociobiology is not unjustly derived, let us examine a specific example of the application of the theory. As stated above, the impetus for sociobiology grew out of the debate regarding the origins of altruism. As might be expected, sociobiologists devised an alternative to the group selection argument (in fact two alternatives) based on the logic of maximizing reproductive fitness. These solutions were termed *kin selection* and *reciprocal altruism*. Both purport to solve the question of how the quality of altruism, which by all appearances reduces fitness, could arise through the process of natural selection where the goal is to maximize fitness.

In reanalyzing the group selection argument, Hamilton (1964) introduced the concept of kin selection. Kin selection is based on the genetic probability of relatives sharing the same genes. Since an individual shares half its genes with both its parents and its siblings, any altruistic act that increases the average genetic fitness of the members of the kin network as a whole, even at the expense of the individual, may enhance the ultimate reproductive success of the genes (Wilson, 1975:177). Thus, according to Hamilton (1964), the assessment of the fitness of a gene (or behavior) must take into account more than the reproductive consequences for the individual organism. What must also be considered is whether the reproductive prospects of any kin are in any way altered. Fitness in this expanded ver-

sion, termed inclusive fitness, refers to "a sum of the consequences for one's own reproduction, plus the consequences for the reproduction of kin multiplied by the degree of relatedness of those kin" (Daly and Wilson, 1978:30). Thus, the sacrifice of one's life for the benefit of two siblings ultimately would confer the same genetic benefit as staying alive and sacrificing one's siblings in terms of reproductive success.

The problem with explaining altruism in terms of kin selection is that altruistic acts do not always occur in the presence of kin; sometimes they are directed toward nonrelatives or strangers. Trivers (1971) solved this dilemma by adding the concept of reciprocal altruism to the now expanding model of sociobiological theory. The concept of reciprocal altruism can best be understood by summarizing Trivers's example. According to Trivers (1971), if you were to save a drowning man who would have a fifty percent chance of dying without your help at a small risk to your own mortality (say five percent), and if at some future time he were to save you from a similar plight where the chances of living and dying were reversed, then you both would have increased your long-range survival chances by forty percent.⁶

There are several problems with these two solutions to the dilemma of altruism, some obvious and others not so obvious. Most critical is that the two theories combined provide a perfect example of the Fallacy of Affirming the Consequent. Both altruistic action that confers no relative advantage to the altruist and action that does may be considered equally adaptive. If an individual is good to his kinsmen, it benefits his own inclusive fitness; if he aids a stranger he benefits in the form of reciprocal altruism. Thus, the phenomena of altruism can be accounted for by two contradictory hypotheses (Sahlins, 1977:84). Any act of altruism can be construed as beneficial to the indi-

⁵ There are some excellent examples of the analysis of the biological origins of behavior, but they do not attempt to identify the underlying evolutionary significance. For example, see Mazur, 1973.

⁶ Sahlins (1977:85) wryly notes that the example of the drowning man is an unfortunate choice "because after all it would be evolutionarily short-sighted to save a man who can't swim on the supposition that he will later rescue you from drowning. . . ."

vidual, either directly by protecting one's genes or indirectly by helping a stranger who might later reciprocate. There are almost no acts of altruism that cannot be explained as adaptive.

The theory of kin selection has a genetic basis that is theoretically calculable, although Wilson (1975:120) admits that "Hamilton's mode of reasoning can be only loosely coupled with the remainder of genetic theory, and the number of predictions it can make is unnecessarily limited." The theory of reciprocal altruism has no genetic basis that can be calculated, and there seem to be no examples of animal behavior that conform to the theory (Wilson, 1975:120). Since the examples of reciprocal altruism consistent with genetic theory only come from human behavior, it seems more logical to suppose that in actuality, there is no genetic basis at all; it is entirely social. Further, if it is true as Wilson notes that there are no animal examples of reciprocal altruism, then how can any of the methods of sociobiology be applied? The only possible way to test the genetic basis of the behavior would be to trace it phylogenetically. However, in contrast to other less complex human social behaviors that may be traceable, reciprocal altruism is not.

Evolutionary Principles in Sociobiology

The view of change implied in sociobiological thought is similar to that in Darwin, random but persistent rather than cataclysmic. The cause of change in both is natural selection acting on variations in individuals. Sociobiologists, along with all modern evolutionary theorists, have been able to hone evolutionary theory to a highly sophisticated degree. In contrast, Darwin who was unaware of Mendel and genetics, was perplexed by the etiology of variation. This was a problem which plagued Darwin throughout his life, as he wrote at one time to Huxley, "You have most cleverly hit on one point, which has greatly troubled me; if, as I must think, external conditions produce little direct effect, what the devil determines each particular variation?" (Darwin 1888:232). So sociobiologists having the advantage of a

knowledge of modern genetic theory are able to produce a more sophisticated view of change than Darwin, including an awareness of the source of variation between individuals.

In contrast to Darwin where order was merely a taxonomic scheme for categorizing empirical instances, sociobiologists view regular change as leading to an increasingly adaptive order, one of behavior in addition to form. Transforming the central issue from one of form to one of behavior appears to be a logically and biologically sound transition. Many studies have identified behaviors where the genetic basis can be calculated. From there it is a simple matter to extend the analogy; if simple behaviors can be identified as structured by the genetic code, then why not complex social behaviors, such as altruism, deceit, aggression, parent-child conflict, even marital infidelity. All can be "explained" by the insistent force of natural selection. However, if the idea of order is preconceived as one that is necessarily adaptive, then existing behaviors can only be explained by their selective advantage. For behaviors to be viewed as nonadaptive or perhaps social in nature, the preconception of adaptiveness must be altered.

In sociobiology the principle of direction has been expanded beyond its original meaning. Darwin recognized that forms could be classified on the basis of complexity. Similarly, sociobiologists can classify behaviors on this same basis. What differs in sociobiology is the assumption that change will nearly always be directed toward maximizing reproductive fitness, that organisms will always be progressing toward the optimum phenotype (Wilson, 1975:24,156). In this sense, the principle of progress has been subtly incorporated with a meaning quite different from that defined earlier. When initially defined by Lewontin, progress was differentiated from direction by the presence of a moral tone. In sociobiological theory, the moral tone has been transformed from the morality of human consciousness to the morality of the gene. In describing the ethical philosophy that characterizes the essence of sociobiology, Wilson (1975:4) states:

Love joins hate; aggression, fear; expansiveness, withdrawal; and so on; in blends designed not to promote the happiness and survival of the individual, but to favor the maximum transmission of the controlling genes.

Thus, the source of morality lies in the struggle of genes to replicate themselves.

CONCLUSION

In his introduction, Wilson (1975:4) criticizes sociology because of its nongenetic approach which proceeds by "unaided intuition, without reference to evolutionary explanations in the true genetic sense." He then modestly continues, "It may not be too much to say that sociology and the other social sciences, as well as the humanities, are the last branches of biology waiting to be included in the Modern Synthesis." Given the fact that there is *no* demonstrable method for identifying the evolutionary significance of human social behavior, it seems highly unlikely that the social sciences and humanities are in imminent danger of losing their independent identities. The method of sociobiology is remarkably tautological, as demonstrated in the discussion of kin selection and reciprocal altruism. Explaining parent-offspring conflict over such matters as going to bed early, studying hard in school, not fighting with siblings, and refraining from gambling, drinking and premarital sex in terms of the ultimate evolutionary significance is intellectual gamesmanship. According to sociobiology, the purpose of socialization is based on the desire of parents to either prepare their children for future genetic altruism or reduce their own time and/or energy expenditure. Children disagree with these parental prescriptions; they generally consider them a drag, because of "their adaptive unconscious perception that such actions would maximize their parents' fitness rather than their own" (Barash, 1977:307). Trivers's (1974) offering of genetic theory as a replacement for what is presently known about childhood socialization does not appear to be immediately threatening to the social sciences, at least as presently formulated.

Sociobiologists have altered the paradigm of evolutionary theory by changing the underlying logic. The concept of differential reproduction has been raised to the highest level of efficiency. Both direction and progress which existed to a minimal degree in Darwin have been added to the model by the emphasis on the maximization of adaptive fitness expressed as an expanded economic metaphor. However, there is no evidence that human behavior represents maximized fitness, nor does it appear to be progressing in that direction. Sociobiology is based on a preconceived notion of change leading to a necessarily adaptive order in which progress is economically calculated in terms of gene survival. Thus, it must be concluded that in terms of method and logic, sociobiology is not applicable to the study of human social behavior.

SIZE AND ADMINISTRATIVE INTENSITY IN NATIONS*

PATRICK D. NOLAN

Pennsylvania State University at Schuylkill Haven

American Sociological Review 1979, Vol. 44 (February):110-125

This paper reports the results of a cross-national study of the relationship between system size and administrative intensity in societies. Predictions that the relative size of government will increase with increases in system size derived from Mayhew and Levinger's (1976a) *density of interaction* model and consistent with an elaboration of Blau's (1970; 1972) *economy of scale* theory of administration are tested with data on 70 nations varying in size, population concentration, and general technological development. A nonmonotonic U-shaped relationship is found between population size and the relative size of government, and this relationship continues to be evidenced when general technological development is controlled. But despite the robustness of the nonmonotonic relationship of administrative intensity with system size, measures of urbanization and relative population concentration are shown to be highly and monotonically related to the relative size of the administrative component of nations. Differences between the two analyses and other problems are discussed, but, with minor qualification, results of these two analyses are interpreted as providing support for the Mayhew-Levinger (1976a) and elaborated Blau (1970; 1972) models and predictions.

The problem of determining the effects of increasing system size on the administrative structure of systems continues to be of interest to sociologists and students of organization. This is evidenced by the publication of two studies which arrive at contradictory conclusions concerning the effects of population size on administrative intensity in social systems (Kasarda [1974a] and Noell [1974a]) as well as by Kimberly's (1976) recent attempt to discern underlying continuities in a diverse and sometimes contradictory literature on formal organizations. Kasarda and Noell, in part, reflect an ongoing debate in the organizational literature (cf. Blau and Schoenherr, 1971:83-90; and Thompson 1967:74); however, their studies also indicate a line of development on this ques-

tion. Both are concerned with the possible extension of size-administrative component generalizations from formal organizations to more diffusely organized systems: communities and societies. Unfortunately, the results of their studies are directly contradictory. Noell maintains that his data clearly demonstrate that such an extension is *warranted*; and Kasarda just as clearly states that such an extension is *unwarranted*. Before a third voice is added to this discussion, it is necessary to examine their respective studies in more detail.

Kasarda (1974a) argued, on the basis of the cross-sectional occupational distributions of 43 nonagricultural nations, that social systems experience an increasing administrative ratio with increasing system size. This clearly challenges the simple extension of economy of scale theories to social systems.¹ In fact, Kasarda's

This is a revised and expanded version of a paper presented at the annual meeting of the American Sociological Association, San Francisco, 1978. The author would like to thank Peter Blau, Eugene Ericksen, John Kasarda, Roy Kass, Dean MacCannell, Dave Martin, Bruce Mayhew, Diane Levy-Miller, Robert K. Miller, Elaine Nolan and several anonymous reviewers for their helpful comments on earlier drafts of this paper and to absolve them of any responsibility for his use of their advice. Thanks are also due to Lindsay Berger and Ruth Squyres for their typing assistance.

¹ In this context, an *economy of scale* is simply a savings in personnel that is engendered by growing organization size. Since there is some irreducible *minimum* of administrative personnel necessary for the functioning of an organization, it is often the case that an increase in organization size does not require a corresponding increase in administrative personnel, and, in fact, may provide for more efficient use of existing personnel. Therefore, a smaller proportion of the organization would be employed in administrative positions. The same reduction in the proportionate size of administration would result if

three-level analysis indicates that some of the reduction in administrative personnel found in formal organizations may be illusory, since declines in management are mitigated by offsetting increases in communications personnel required to coordinate activities in larger systems. This argument has gained considerable theoretical support from Mayhew and Levinger's (1976a) paper which posits that the expected level of interaction in a system is a multiplicative, rather than an additive, function of system size.² From this theoretical perspective, the increasing problems of coordination engendered by a multiplicatively increasing density of interaction might explain the disproportionate growth in administration found in some large formal organizations and social systems.

Noell's (1974a) study of the 50 state governments in the United States directly contradicts Kasarda's findings. Noell's data indicate that the proportion employed in state governments *declines* with increasing system size. He thus concludes that theories of an economy of scale are applicable across system levels. These two contradictory conclusions in themselves indicate that the issue warrants further study, but there are methodological limitations which also should be considered. Kasarda studied the problem cross-nationally but he employed an *indirect* indicator of the size of the administrative subsystem (i.e., the proportion of the labor force employed in administrative positions). Noell used a more direct indicator of the size of the administrative subsystem (i.e., the proportion employed in government) but he limited his study to one country, the United States, which cannot be considered typical or representative of national organizations, and, therefore, may not give an accurate depiction of the general relationship between

the two variables.³ This paper will combine what are felt to be the respective strengths of these two studies. It will use government employment as its indicator of the size of the administrative component of societies, and it will examine the relationship cross-nationally in 70 nations which vary in size, technological development, and population concentration.

As suggested by Mayhew and Levinger (1976a), the expectation is that increasing interaction will increase problems of coordination and control and since governments are the *subsystems specifically charged with monitoring and responding to system-spanning problems*, they can be expected to expand in size to meet these growing contingencies at the national and regional level. Since the rate of interaction and its attendant problems are predicted to be increasing at a faster rate than the population is growing, government is expected to grow at a faster rate than population. Therefore, as the size of the system increases government employment should begin to constitute a greater proportion of the population or work force. Growth in government, however, is not the only way that a government can increase its capacity to coordinate. We are not maintaining, therefore, that growth in employment is the only way that governments can be expected to respond to increasing problems of administration, but rather that it is a reasonable place to look for a society's response to an increase in problems of administration.

At first glance such a prediction appears to contradict the extension economy of scale theories to social systems, but further examination of one economy of scale theory suggests this need not be the case. Blau's (1970; 1972) discussion of the indirect effects of size on administration contends that economies of scale are, in some measure, offset by the increasing complexity that size introduces into the system via differentiation (this is also at the heart of Kasarda's [1974a] argument regarding increased communication needs in complex systems). Blau maintains,

administrative personnel grew at a slower rate than overall organization population. In such cases, the administrative component would increase in *absolute* numbers while declining as a proportion of the total population of the organization.

² Kasarda's (1974a) hypotheses originally were derived from theories of nonproportional growth put forth by Thompson (1917) and by Boulding (1953).

³ Noell (1974a:555) is aware of some of the limitations on the generalizability of his findings to other independent and federal systems.

therefore, that while initial increases in size and differentiation produce substantial decreases in administrative ratios, further increases in size are accompanied by ever smaller declines in administration, presumably because increasing complexity introduces increasing problems of coordination and communication. In Blau's data on formal organizations, these indirect effects never fully counteract the direct effects which reduce administration, although they do, he argues, begin to attenuate the slope of the curve. It is important to keep in mind that the upper size limit of the organizations that Blau examined was well below that of even the smallest nation. It is thus conceivable and consistent with Blau's theory to posit that *in larger systems the indirect effect of size might begin to outweigh the direct effect, and a reversal of the trend of declining administration would evidence itself*. Blau (1974:16, emphasis added), in fact, alludes to this possibility:

Within organizations, structural differentiation, by enhancing problems of coordination and communication, enlarges the administrative component. The same may well be true for entire societies. Specifically, the increasing differentiation of societies may *expand the proportion of civil servants* and of their labor force in other administrative positions.

Thus Blau's theory, rather than being discredited by such a finding at the societal level would, in fact, be elaborated empirically by demonstrating the effects of size over a greater range of the variables.⁴ Also, considering the problem in

this light makes it clear that even the demonstration of a decline in the *rate* at which administrative ratio decreases with increases in the size of social systems provides plausible, if not compelling, evidence for our proposition. Stronger evidence, of course, would be provided if it could be demonstrated that administrative ratio increases in larger systems, for this would indicate that the decline in administration had not only been attenuated, but in fact had been arrested and reversed.

Given the considerable evidence in support of economy of scale theories found in organization research, it makes sense to test this density of interaction hypothesis against them. Orienting ourselves to economy of scale theories establishes an explicit *gradient* of support for the hypothesis, and this allows consistent inferences to be drawn from the data.⁵

DATA AND METHODS

For purposes of the present analysis, system size is operationalized by population, since this is the most basic indicator of the system's conduciveness as well as its limitations on interaction density according to the Mayhew-Levinger model

labor in the form of structural differentiation, *not* the distribution of individuals in general occupational categories. Of concern would be the number of occupational categories or organizations, not the distribution of individuals in them.

In any event, when the effects of size on the administrative component are examined, one can assume that this increase in size produces an increasing division of labor. The division of labor, therefore, can be seen as an unmeasured intervening variable.

⁵ For instance,

- strong support: proportion in administration is *positively* and highly correlated with size;
- moderate support: proportion in administration is *positively*, but not highly, correlated with size;
- qualified support: proportion in administration is *not negatively* correlated with size.

Of course provisions could be made for changes in the direction or sign of the relationship over the range of size—certainly a shift from negative to positive as size increases is in line with the theory, whereas a shift from zero or positive to negative would not be. (Zero values would be interpreted in the context in which they might appear in the analysis—as in the cases of specification.)

⁴ Given the strong empirical and theoretical connection between size and the division of labor (e.g., Mayhew et al., 1972; Durkheim, 1964; Blau and Schoenherr, 1971), there is no incompatibility between the density of interaction hypothesis discussed here, and theories that see the division of labor as generating problems which require a greater development of mechanisms of coordination and integration to maintain system integrity. In fact, moving to this level of analysis (which is more sociological), one could generate an expectation for the density of interaction between *structural units* rather than individuals. The density of interaction hypothesis should apply at this level (i.e., interaction between units should increase at a multiplicative rate), and it is conceivable that the hypothesis would have more explanatory power at this level. To do so, however, would require a measure of the *division of*

(1976a). And, although there has been some disagreement as to whether government employment or the percent of the labor force employed in administrative positions provides the more accurate assessment of administration at the societal level (Noell, 1974b; Kasarda 1974b), it is arguable that the level of government employment is at least one reasonable place to look for a society's response to problems of regulation and coordination posed by increasing levels of interaction and system activity.

In gathering government employment data as an index of the size administrative component of the nation, the intent was to get the most accurate measure of total civilian government employment (salary and wage workers) including local, regional, and central government where reported separately.⁶ Rupprecht (1974) provides the most comprehensive argument as to why total government employment is the best cross-national indicator of the size of government. He argues that it is superior to revenue and taxation measures in indicating size, and that it is clearly the most comparable measure available cross culturally. This is not to say, however that the measure is without

limitations and problems. Kasarda (1974b) has raised objections and has indicated the heterogeneity of government employment in somewhat the same manner that Rushing (1966) pointed out the heterogeneity in the administrative component of formal organizations. There are undoubtedly other sources of error and slippage in this indicator due to its generation from secondary sources (Webb et al., 1966), but multiple sources were sought, and discrepancies between sources were investigated in order to get the most accurate assessment. The date for the government figure was used then to determine the relevant date of the independent variables. In some cases it was necessary to adjust figures by determining the number of noncivilian personnel and subtracting them from government in order to make measures more comparable cross nationally.

In contrast to Kasarda (1974b), Noell (1974b) argues for the use of government employment as the best indicator of administration at the societal level, and although the relative utilities of these measures cannot be resolved here (each would seem to have its advantages and disadvantages), use of government as an indicator of the size of administration in a cross-national context will allow us to determine if the discrepancy between Noell (1974a) and Kasarda (1974a) is due merely to their respective choice of indicators. In all, cross-sectional data on government employment were obtained from secondary sources for 70 nations.⁷ Of particular use

⁶ In order to avoid confusion, it should be clearly understood that when we are dealing with the size of government, we are dealing with what might be termed the implementation structure, we are making no statements about decision making in these systems. The number of persons that are involved in making decisions or in setting policy is clearly independent of the number of persons needed to administer or implement those decisions and policies.

A growing government sector may become increasingly unwieldy, but no one would argue that a system is more democratic simply because more people are required to run it. This also posits that no contradiction exists between the predictions made here of an increasing proportion employed in government and Mayhew (1973) and Mayhew and Levinger's (1973; 1976b) theoretical argument for a declining proportion in the "ruling elite." The two are analytically separable questions. What is argued here is that increased coordination problems will put pressure on the system to expand its administrative capacity by increasing employment—it does not imply that more persons will thereby be involved in making decisions and setting policy. It is conceivable that a growing government sector could be implementing policies that are set by a proportionately declining "elite." Failure to separate these two questions can only result in unproductive debate and confusion.

⁷ Although this analysis relies on cross-sectional data, examination of over-time data has shown that in the United States government employment has increased at a faster rate than population at both the federal and the local level (Lenski and Lenski, 1974: 359–60; Fabricant, 1949; 1952). Labor force statistics for Canada and Great Britain indicate that this same disproportionate growth in government has taken place in these countries as well.

In Canada the percent of total population employed by government has increased from .27 in 1912 (earliest total figure) to 1.0 in 1959. In Great Britain employment in "Public Administration" expressed as a percent of the population of England and Wales has increased from .27 in 1840 to 1.2 in 1921 (when the classification system was changed).

Thus, on the basis of readily available over-time data, one would conclude that government has grown at a faster rate than population in the United

in generating these data were the *Worldmark Encyclopedia of Nations*, *The Statesman's Yearbook*, the *Europa Yearbook*, and Rupprecht (1974). In addition to these compilations, the statistical yearbooks of the various nations that were held by the Temple University Library, University of Pennsylvania Library, the Library of Congress, and the Department of Labor were directly consulted (where language and assistance permitted) in the collection of government data. The 70 nations for which data were available comprise roughly half of the independent and quasi-independent nations in the world (136) as determined by the U.S. Department of State in 1969.⁸ The only known bias in the data set is the exclusion of most communist or socialist nations. This is a result of the fact that most socialist nations do not report a government employment figure that is sufficiently distinct from industrial employment. Lack of probability sampling and the exclusion of socialist nations does not necessarily affect the validity of this study but it does limit the generalizability of the findings.

Since it is the relative rather than the absolute size of government that is of interest, this figure is expressed as a percent or proportion of the total population.

States, Canada, and Great Britain. The fact that such diachronic data are limited to western, industrialized nations of considerable size, makes it important to examine the question cross-nationally, in different types of nations, even if that examination is synchronic. This is necessary to avoid inferring a "universal" process from a limited and perhaps culturally biased sample of nations. Sources: Mitchell, 1965; Urquhart, 1962.

⁸ The data set consists of: Argentina, Australia, Bahrain, Barbados, Belgium, Bolivia, Botswana, Burma, Burundi, Cambodia, Cameroon, Canada, Central African Republic, Chile, Columbia, Cyprus, Dahomey, Ecuador, Ethiopia, Finland, France, Gambia, West Germany, Ghana, India, Iraq, Ireland, Israel, Italy, Ivory Coast, Japan, Kenya, South Korea, Kuwait, Madagascar, Malaysian Federation, Malawi, Malta, Mauritania, Mexico, Morocco, Netherlands, New Zealand, Norway, Paraguay, Peru, Puerto Rico, Southern Rhodesia, Romania, Rwanda, Saudi Arabia, Senegal, Sierra Leone, Singapore, Republic of South Africa, Swaziland, Sweden, Syria, Tanzania, Togo, Trinidad and Tobago, Uganda, Upper Volta, United Kingdom, United States, Venezuela, Western Samoa, Southern Yemen, Yugoslavia, Zambia.

Further information on the data set is available in Nolan (1978) and from the author on request.

This measure is analogous to the administrative ratio that has been used as an index of administrative intensity in formal organization research. And despite their long history in the study of organizations and macrostructures, ratio variables and the administrative ratio in particular have become the subject of some controversy in methodological and statistical circles (Freeman and Kronenfeld, 1973; Fuguitt and Lieberman, 1974; and Schuessler, 1974). This controversy, therefore, needs to be considered before proceeding to the analyses of our data. It is interesting that the issue is considered to be a statistical one, given that both Fuguitt and Lieberman (1974:132-3) and Schuessler (1974:394-5) point out that the determination of whether to use ratio variables or the administrative ratio in a given research context is determined by *theoretical* and *conceptual* concerns, rather than statistical or technical concerns. This is clearly evident in Fuguitt and Lieberman's (1974) discussion of the issue of "spurious correlation," as originally raised by Pearson (1897), where they state:

A number have pointed out that there is nothing intrinsically spurious about the correlation, though interpretations may indeed be spurious, *as in inferring from a ratio correlation the size or direction of a component correlation or vice versa. A basic distinction here is whether one's major interest really focuses on the component measures.* (Fuguitt and Lieberman, 1974:132, emphasis added)

They argue that if in fact one's concern is with the ratio itself and not its components, then the presence of a common term is not problematic. It is the *theoretical concern* and the *substantive* focus that determines if ratio variables are appropriate, not technical statistical concerns (Schuessler, 1974:395). In reiterating this contention in their conclusion, Fuguitt and Lieberman (1974:141, emphasis added) add on a "belief" and a suggestion:

First, an argument can be made that spurious correlation is not an issue in correlating ratio or difference terms, provided that one's interest is exclusively in the composite variables rather than in the components. *We believe*, however, that it is usually difficult to maintain that position; problems *can* be reformulated in terms of component variables,

or in any event the relation between the components and the composite variables *may be profitably explored*.

Fuguitt and Lieberman's "belief" would appear to be the belief that sociologists cannot be genuinely interested in the study of social structures and the use of structural variables, and does not detract from the fact that they have themselves argued that the problem is a theoretical and conceptual issue rather than a simple technical or statistical one. The determination of the use of a ratio must stand or fall on the basis of its theoretical justification.

Clearly the interest in administrative ratio expressed here is the use of it as an indicator of the relative size of the administrative component of the nation. It is to be used to determine the effects of system size (scale) on the administrative component, not the effects of increasing population on administrative employment. Although the distinction may be subtle, this is not merely hair-splitting. The focus is on administrative ratio as a *structural variable*, and it differs from the managerial concern with the effects of increasing production employment on overhead or nonproductive personnel. It is not used to enable the prediction of the number of government employees from the size of the population, but rather to see the effects of increasing population on the relative size of the administrative component of the nation. Since interest is in the composite rather than the components, use of administrative ratio would appear to meet Schuessler's as well as Fuguitt and Lieberman's criteria of acceptability. The fact that the hypothesis *can* be stated in other terms is another matter.

Other critics, notably Freeman and Kronenfeld (1973), have added to this controversy by claiming that correlations between size and administrative ratio are an "artifact" and can be produced by "random noise." This issue of "definitional dependency" or "built in" *negative* association between these variables has been seen to result from the assumptions these critics make rather than the intrinsic properties of the variables (Mayhew and Levinger, 1976b:1018; MacMillan, 1975;

Kasarda and Nolan, 1978), but since knowledge of this is not widespread, it is fortunate that these critics have proposed alternative methods which they claim are free of this problem. One of these methods which was proposed also by Akers and Campbell (1970) has been used to determine the relative growth rates of a variety of phenomena including: the organs of cats, size and functional differentiation in preindustrial and industrial societies, and even the relative growth rates of populations, legislatures, and governments (Svalastoga, 1974). Since this method is presumably free of the "problems" Freeman and Kronenfeld (1973) have discussed, and there is neither the time nor the space here to consider the issue more fully, this alternative method will be used to check the results of the analyses that employ administrative ratio (see fn. 13).

Two indicators of technological development also were gathered for use in the analysis: (1) the percent of the total population engaged in agriculture (United Nations, 1971: Table 5) and (2) the energy consumed per capita in kilograms coal equivalent (United Nations, 1973: Table 137). Employing these measures as controls will allow us to determine if size has an effect on administrative ratio that is independent of general technological development. Measures based on the areal expanse of the system also will be introduced as controls in this analysis. In addition, because we are sensitive to the fact that the relative concentration of a population is as important as the size of the population, we will examine the relationship between administrative intensity and two direct measures of population size and concentration (cf. Taylor and Hudson, 1972: Tables 4.1 and 4.2, respectively):

- (1) URBAN, the percent of the population residing in cities of 100,000 or more;
- (2) CONCENT, an index of the relative concentration of population over the area of the country varying from .000 to 1.0.

The use of these variables as indicators of structural properties provides the same

Table 1. Correlations of the Percent Employed in Government and Population Size All Nations (N = 70)

defense for these ratio variables that was given for the use of the administrative ratio itself.

ANALYSIS AND DISCUSSION

The zero-order product-moment correlations shown in Table 1 between population and the proportionate size of government offer little evidence of relationship. Certainly no strong *linear* relationship is present. The simple correlation between size and the percent employed in government is .09, and when the variables are logarithmically transformed to detect simple curvilinearity, the coefficients remain small, and in one case change signs. The lack of probability sampling prevents one from relying too heavily on significance figures in drawing conclusions.⁹ But since Pearson-correlation is only capable of measuring the degree of *linear* association, and logarithmic transformations will only detect certain forms of curvilinearity, examination of the scatterplot is always indicated before concluding that no relationship exists (Blalock, 1960:312). Examination of the scatterplots suggested that the relationship was not only curvilinear, but was also *nonmonotonic*. It appeared to be a rather flattened U-shaped curve with an inflection approximately at the medium of population size. In order to test this impression, the data were broken into four size categories and the mean percent in government was computed for each category.¹⁰ This distri-

bution of the means, shown in Table 2, confirms the impression gleaned from the scatterplots.

The lowest size category has the highest mean government employment. The second size category has the lowest mean government employment with the third and fourth category means displaying a progressive increase. Since the inflection of the curve falls approximately at the median, a further test of nonmonotonic relationship would be provided by performing separate analyses on the subpopulations when the data are split at the median (or approximate point of inflection). For convenience correlations calculated in these subpopulations are referred to as split correlations. The use of separate analyses for curvilinear relationships is suggested by Heise (1975:91-2). He states that curvilinearity of this type can be dealt with simply by performing two separate linear analyses, one for the lower values

the means were plotted, the same general pattern emerged indicating that the pattern is not merely an artifact of our choice of cut-points. If we use Kasarda's purposive categories (adapted to his data, not *ours*), we find some interesting differences in the data on developed nations.

Using Kasarda's categories:

Lowest to 500,000 = 1;
500,001 to 5,000,000 = 2;
5,000,001 to 25,000,000 = 3;
25,000,001 to Highest = 4.

The category means of all nations are:
3.262, 1.884, 1.899, 3.127
N=6 N=25 N=29 N=10.

Note the interesting differences between nonagricultural and industrial nations:

Industrial More than 2,000 kilos coal
(N=24)

1.910 3.069 3.500 3.867
N=2 N=9 N=7 N=6

Nonagricultural
(N=33)

4.252 3.455 3.051 3.429
N=3 N=10 N=13 N=7

The shifting of a few additional cases in this instance *does* affect the pattern of the relationship.

⁹ Since we are not dealing with a probability sample in this analysis, significance figures have no direct or simple interpretation. They are reported for the reader's interest and because it is customary to do so even where they are not really warranted (Noell, 1974a; Sjoberg and Nett, 1968:281-4).

¹⁰ We are sensitive to the fact that how one categorizes (i.e., the choice of cut-points) the data may influence the means. We used quartiles not because of any intrinsic property or a priori knowledge of the means, but rather because of the small number of cases. When the data were broken into deciles and

Table 2. Mean Percent Government Employment in Population Size Categories for all Nations Combined and for Nations Classified by General Technological Development

SIZE CATEGORY	MEAN PERCENT IN GOVERNMENT	N	MEAN PERCENT IN GOVERNMENT	N
ALL NATIONS				
140,000– 2,550,000	2.743	18		
2,550,001– 5,750,000	1.250	17		
5,750,001– 15,000,000	2.180	18		
15,000,001–504,000,000	2.539	17		
DEVELOPED NATIONS

2,350,001– 5,200,000	.705	10	.705	10
5,200,001– 10,900,000	1.047	9	1.415	13
10,900,001–504,000,000	1.456	9	1.674	12

(of size), and another for larger values (of size). This procedure is adopted here in lieu of developing a curve to fit the overall relationship between population size and the percent employed by government.

The split correlations in Table 3 indicate that the direction of the relationship reverses at the median. At the lower end of the size scale a strong negative relationship is evidenced, while in larger systems the relationship is positive. The distribution of means and the correlations offer consistent evidence of a nonmonotonic relationship between size and the proportion employed in government. The form of this relationship suggests that a threshold effect may be operating. This would indicate that after some critical value of size is reached, the direction of the relationship reverses. Thus the question as to whether economies of scale do or do not obtain may have to be specified by size level. This is especially important for this analysis because one goal of this research is to test for possible isomorphism across system levels. If the specification continues to hold up in later analysis it may well be one of the most important findings, but before over-interpreting this ef-

fect, the relationship should be examined when technology is controlled.

Kasarda's (1974a:24) method of case selection suggests a possible use for our first measure of general technological development: nations in which less than half of the population is engaged in agriculture will be classified as developed, and those in which more than half are engaged in agriculture can be classified as undeveloped. This procedure results in 33 nations being classified as developed (nonagricultural) and 37 nations being classified as undeveloped (agricultural).

Table 2 shows that the same nonmonotonic pattern is present even though the mean level of employment in government is higher for nonagricultural nations than for all nations. The split correlations in Table 3 also are similar to those found in all nations. They are negative for small systems and positive for large systems. Nonagricultural nations thus exhibit the same pattern of relationship that was found in all 70 nations, and while the correlations are rather small at the upper end of the size scale, the pattern of relationship appears to be holding when technology is, in some measure, controlled. The

complementary subset of nations, those in which 50% or more of the population is engaged in agriculture, also provide comparable results. In Table 2 the same pattern of mean government employment for the different size categories is present and in Table 3 the split correlations are negative for smaller systems and positive for larger systems.

An alternative control for general technological development is provided by the per capita energy consumption in kilograms of coal equivalent. Following Lenski and Lenski (1974:296), 2,000 kilograms per capita is used as a rough cutting point between developed (industrial) and undeveloped (nonindustrial) nations. This results in 24 nations being classified as developed and 46 being classified undeveloped. The same nonmonotonic pattern of relationship between size and administration emerges in these subcategories of nations as is clearly shown in Tables 2 and 3. The employment of this second measure of development does not materially alter the pattern of relationship initially found in the data. There are some minor differences in the data sets when the different measures of development are used, but the pattern of relationship remains the same. This is illustrated quite clearly in a combined plotting of the category means displayed in Figure 1. The same U-shaped pattern is found in all subsets of the data. The procedures for grouping the data into developed and undeveloped make it impossible for this pattern to be due to the same one or two extreme values.

The fact that this nonmonotonic relationship continues to be present when development is introduced as a control suggests that this pattern of effect is at least partially independent of general technological development. And although there is considerable overlap between the data sets when alternative indicators of development are used—the employment of either indicator results in the same pattern of relationship in two *independent* data sets: one consisting of developed nations and the other consisting of undeveloped nations. The fact that developed nations have, on the average, a higher level of administration than undeveloped na-

Figure 1. The mean level of government employment by population size quartile

tions is consistent with a major constraint on the size of government—the wealth of the system and its ability to support tertiary employment. But finding the same pattern of relationship within these two sets of nations indicates that although technology may operate as a general constraint on the system, it does not explain the nonmonotonic trend of government employment that accompanies increasing population size.¹¹ One could certainly

argue that an economy of scale is manifested in small nations, but in the face of the evidence adduced thus far, one could not maintain that economies of scale continue to operate in large systems. This change in direction, or nonmonotonicity, while not directly predicted by the Mayhew-Levinger model (although a reversal at some point is suggested by Blau [1970; 1972] and found by Kasarda [1974a]), may well be compatible with it,

¹¹ The persistent nonmonotonic trend found here, caused much consternation and brought up the possibility that some of the choices of indicators and

the adjustments for military personnel might conceivably have caused us to systematically under- and overestimate the relative size of governments for

and with the hypothesis developed from it.¹² The addition of a tipping-point may well complicate the discussion, but it does not disconfirm the hypothesis.

It was hypothesized that the proportion in government would increase with increasing system size, and there is at least some evidence that is the case; but only after some critical value of size is reached. This would suggest that there is, in fact, an economy of scale operating until some critical tipping-point is reached, at which point the trend reverses and the proportion in government begins to *increase* with further increase in size.¹³ The notion of

tipping-point or critical value of size is not totally unexpected in organizational research. Other theorists and researchers have suspected them, and this was at least part of Kasarda's motivation for doing a three-level analysis of the effects of size on administration. It is not surprising to find only a small increase in the relative size of administration in large systems, indicating *attenuation* and *reversal* of the trend of declining administration, but it is surprising that this increase is only manifested at the upper end of the size distribution of nations. Blau's model is consis-

certain size categories. Examination of the data indicated that this was not the case, however. Using a reduced set of data comprised of the 48 nations which were not adjusted or in any way affected by our collection choices, produced nearly identical means for the various subsets of nations, and would not cause the modification of any of the conclusions presented earlier. Even the removal of "outliers" in categories did not reduce the nonmonotonic trend appreciably. The respective category means in the reduced data set were:

All nations: 3.01 (N=12), 1.63 (N=10), 2.25 (N=13), 2.84 (N=13);

Industrial: 4.34 (N=5), 1.73 (N=3), 3.91 (N=5), 4.02 (N=5);

Nonindustrial: 2.60 (N=7), .88 (N=4), 1.44 (N=9), 1.73 (N=10);

Nonagricultural: 5.46 (N=6), 1.59 (N=4), 3.12 (N=8), 3.56 (N=7);

Agricultural: 1.19 (N=6), .88 (N=4), 1.27 (N=7), 1.67 (N=6).

This, of course, does not remove indigenous error of which we are not aware; but the consistency of the pattern and the number of opportunities we have given it to be disproved makes it less and less plausible that this is an artifact.

¹² Anderson and Warkov (1961:26-7) also infer from the slope of the decline in administrative ratio with increasing hospital size that the relationship between size and administration in hospitals may be U-shaped.

¹³ As indicated in the text, critics who have contended that there *may be* statistical or methodological problems that result from correlating system size with the administrative ratio of a system have offered alternative methods of analysis that are free of those "problems." One such method originally proposed by Akers and Campbell (1970) and discussed by Freeman and Kronenfeld (1973) is to regress the logarithm of the number of administrators on the logarithm of system size. This double-logarithmic transformation allows one to determine whether the administrative component grows proportionately or disproportionately with increases in system size simply by inspecting the regression coefficient. If the regression coefficient is less than 1.0, it indicates that administrative employment grows at a slower rate

than the organization increases in size. If the coefficient is greater than 1.0 it indicates that administrative employment grows at a faster rate than the organization increases in size. The first instance illustrates an *economy of scale* in administration, and the second indicates a *diseconomy of scale* in administration (Moore, 1975). If the regression coefficient is 1.0, it indicates that administrative employment grows proportionately with increases in system size. This double-logarithmic transformation has been used in biological contexts to test the "principle of allometry (i.e., that parts tend to maintain relative growth rates which when measured as proportion of the relative growth of the total system are invariant)" (Svalastoga, 1974). Because of their identity with the econometricians' *elasticity coefficients* (Johnston, 1972:51-2), the slopes of the regression equations estimated with the doubly logarithmically transformed data can be interpreted as a measure of their relative growth rates. Thus a slope of 1.00 indicates that the two variables change proportionately, or that Y changes at a rate of 100% for every change in X. A slope of 1.6 would indicate that Y grew 60% faster than X, and a slope of .60 would indicate that Y grew at only 60% of the rate of X (Svalastoga, 1974:55). This broadens the interpretation put on this coefficient by Freeman and Kronenfeld (1973), and may prove useful in interpreting the coefficients reported below.

Since this method detects departures from *proportionality*, it can be used to verify the results of the analyses that employed administrative ratio to determine the effects of increasing size on the relative size of the administrative component of nations. The coefficients displayed below confirm the conclusions drawn earlier. Government employment increases at a slower rate than population size in small societies ($b=.50477$) while in large societies it increases at a faster rate than population ($b=1.26928$). Further analysis also indicates that the nonmonotonic trend is present within the various categories of general technological development. The respective slopes are: agricultural, small $b=.57635$, large $b=1.24063$; nonindustrial, small $b=.37897$, large $b=1.19073$; nonagricultural, small $b=.66832$, large $b=1.02299$; industrial, small $b=.82908$, large $b=1.07835$. A more complete examination of the results of this method of analysis and its rationale are provided in Nolan (1978).

tent with such a threshold, but one might have expected it to be reached at a much lower value of size, perhaps below that of even a small nation. Instead the relative size of administration in societies of increasing size corresponds, in part, to the distribution of administrative ratio found in organizations of increasing size. The difference being that there is a mild increase in administration in the upper size range for nations, while in formal organizations there was only an attenuation in the rate at which the administrative ratio declined.

However, if one is willing to grant that with increasing size and its attendant economies of scale that administrative capacity increases, then one is forced to conclude that the administrative ratio is growing at the same time that it is becoming more *effective*. This would appear to have been the case in the United States, 1900–1949 (Fabricant, 1949; 1952).

Review of some factors affecting the trend of government productivity—the use of improved technology and equipment, the spread of the merit system, the introduction of centralized purchasing, and various other advances in public administration—leaves the strong impression that the savings effected by their means have been far from negligible. (Fabricant, 1949:24)

... [T]he long term trend in government's productivity has probably been upward. (Fabricant, 1949:25)

This leads Fabricant to conclude that even in the much maligned U.S. government bureaucracy, little, if any, increase in government employment has been caused by declining output. Quite the contrary, he maintains that output has probably increased, and Downs (1967) makes a similar point, in a more general context when he argues that bureaus suffer from the fact that they are constantly compared with an idealized and unrealistic picture about how private organizations operate and how employees in them function. The tireless, dedicated employee is a myth in private industry and such comparisons are highly misleading; a comparison of actual outputs would be quite interesting, and conceivably might indicate that the reverse is closer to the truth.

A quite different pattern of relationship

emerges, however, with the more direct indicators of population size and concentration. Urbanization is positively related to the relative size of government, and unlike the relationship with population size, this relationship appears to be monotonic. The correlation for all 70 nations is .54, indicating that this variable accounts for about 30% of the variance in the relative size of government. In small systems, those with populations less than 5,750,000, the relationship is slightly attenuated but it does not change sign ($r=.44$). The correlation for small societies may be lower because the cut point of 100,000 would make the urbanization measure more sensitive to variation in large systems, only at the expense of desensitizing it to variation in small systems. This is a result of the fact that nations that do not have a single city of that size are all classified as being 0% urban even though they may differ in population concentration. In large systems, those with populations greater than 5,750,000, where the measure is expected to be more sensitive to actual variation in size and concentration, the relationship increases to $r=.69$, indicating that nearly 47% of the variation in the relative size of government is explained by urbanization. The alternative measure of population distribution confirms the relationship found with urbanization. The correlation between *concent*, an indicator of the relative concentration of people, and the relative size of government is .30 for all systems (examination of the scattergram indicates that an outlier attenuates the overall correlation) and this correlation is .55 in small societies and .69 in large societies. The results using these two more direct indicators of population concentration and size are therefore different than those that examined the effects of size alone. These associations might be larger and their monotonicity may be due to the fact that these measures simultaneously take into account both population size and population concentration and this might suggest that controlling for population concentration would wipe out the nonmonotonic relationship between population size and administrative intensity. However in Table 5 the same nonmonotonic pattern is clearly present

Table 4. Zero-Order Correlations of the Percent Employed in Government with Measures of Urbanization and Population Concentration and Partial Correlations Controlling for General Technological Development

when controls for concentration are introduced. The nonmonotonic relationship between size and administrative intensity, therefore, is not explained by the relative concentration of the population, and it also can be seen in Table 4 that the monotonic relationship between administrative ratio and direct measures of size and concentration is not explained by general technological development.

Although there are differences between the two analyses of the effects of population size and concentration on administrative intensity, the results of both analyses are consistent with predictions made from the density of interaction model developed by Mayhew and Levinger (1976a) and with Blau's (1970; 1972) formal theory of differentiation. The nonmonotonicity of the size-administrative intensity relationship might be taken as an indication that social systems constitute a separate level of analysis, rather than being merely overly large formal organizations. This would explain why the full range of the size-administrative intensity relationship is found when the analysis is performed on social systems. Being a separate level of analysis (*sui generis*), social systems do not represent merely the upper range of the organization size scale. Whether this

is the case or not, however, in large societies, regardless of technological development, increases in size produce disproportionate increases in government employment. The fact that urbanization and population concentration measures evidence a strong monotonic relationship with administrative intensity suggests that the ecological development of the system has a direct effect on the level of administration which is independent of size.¹⁴

The primary objective of this research has been to determine the effects of increasing system size on administration, but it has been assumed from the outset

¹⁴ This idea is supported by the fact that associations between the percent urban and the proportion employed in government are higher ($r=.66$) than those between the total urban population (percent urban \times population) and the proportion employed in government ($r=.30$, and $r=.35$ with the log of total urban population). Even when both the total urban population and the proportion employed in government are converted to logarithms to correct for skew, the association only increases to .47, while the association between the log of the proportion employed in government and the percent urban is .67. These correlations indicate that the *degree* or *extent* of urbanization is a better predictor of government size than is the actual size of the urban population. Controlling for population concentration or the percent urban does not remove the nonmonotonic pattern of relationship between population size and the proportion employed in government, however.

Table 5. Partial Correlations of the Log of Population Size and the Percent Employed in Government Controlling Relative Population Concentration and Average Distance^a

	CONTROLLING FOR CONCENTRATION	CONTROLLING FOR AVERAGE DISTANCE	CONTROLLING FOR CONCENTRATION AND AVERAGE DISTANCE
	POPLOG	POPLOG	POPLOG
ALL NATIONS PERCENT IN GOVERNMENT	.30 (55) ^b	.08 ^c (55)	.13 ^c (54)
SMALL NATIONS PERCENT IN GOVERNMENT	-.43 (20)	-.37 (20)	-.40 (19)
LARGE NATIONS PERCENT IN GOVERNMENT	.43 (32)	.10 ^c (32)	.32 (31)

NOTE: Population cutting point 5,750,000.

^a *Average Distance* is computed in the following way: .52 times the square root of area. Under the assumption that people are uniformly distributed over a square area, this figure reflects the average distance between random pairs in that system. Thus it is an attempt to take into account (a priori) the effects of the average distance between people. For a further discussion of this measure and its limitations see Nolan (1978), for a discussion of its theoretical importance in the density of interaction model see Mayhew and Levinger (1976a).

^b Degrees of freedom in parenthesis.

^c Not significant at the .05 level.

that *Development* is also an important determinant of a system's need and ability to support a large administrative component. Levels of industrial and economic development are an important determinant of the system's ability to produce a surplus and maintain a large tertiary sector, and GNP itself is in part an index of the amount of commercial activity in the system. Likewise a high degree of agricultural employment can be seen not only as an indicator of population dispersal but also as an indication that commercial activity is at a lower level than in a more industrial or developed system. Development therefore was anticipated to have an effect on both the level of system activity and on the relative size of governments. This assumption has been borne out in both analyses presented here. Yet it is obviously the case that the choice of indicators used in these analyses gives differential advantage to either system size or system development as an explanatory variable. Examining only the effects of size (population), shortchanges size in the competition to explain variance in the administrative ratio, while the use of an urbanization measure as an index of size and population concentration obviously shortchanges system development since

the measure does not merely reflect population size and concentration but also is related strongly to the system's level of development. The empirical interrelation of these two sets of variables makes it difficult to disentangle and ascertain the relative importance of these analytically separable determinants of administrative growth, but this analysis has presented evidence that both affect the relative size of the administrative component of nations.

CONCLUSIONS

This cross-sectional analysis has presented evidence that at the societal level of analysis a nonmonotonic U-shaped relationship exists between size and administrative intensity. Mayhew and Levinger's (1976a) argument that interaction density can be expected to increase with increases in system size, and Blau's (1970; 1972) argument that structural complexity can be expected to increase with increases in system size have been offered as explanations for the failure of large societies to continue to display economies of scale in administration after a size tipping point is reached. It is thus the case with administrative intensity, and

perhaps with other organizational traits as well, that isomorphism between formal organizations and societies cannot be assumed to exist even though principles of organization continue to hold. Thus the effects of the scale of organization require that extensions of formal organization findings and generalizations be investigated empirically rather than being assumed to hold logically. It also can be seen from this analysis that the discrepancy between Kasarda's (1974a) findings and Noell's (1974a) findings are not merely the result of their respective choice of indicators of administrative intensity (Kasarda, 1947b; Noell, 1974b), since we have here confirmed Kasarda's hypothesis in an analysis that employs Noell's indicator of administration. The fact that disproportionate increases in government employment are found in a number of large societies at varying levels of general technological development also indicates that this growth in administration results at least in part from the imperatives of system size and is not wholly a result of specific political programs, histories, or technological advance as some observers of western industrial societies have implied (Fabricant, 1949; 1952; Lenski and Lenski, 1974).

POSSIBLE CAUSES OF THE APPARENT SEX DIFFERENCES IN PHYSICAL HEALTH: AN EMPIRICAL INVESTIGATION*

WALTER R. GOVE
Vanderbilt University

MICHAEL HUGHES
Vanderbilt University

American Sociological Review 1979, Vol. 44 (February):126-146

For the past fifty years it has been consistently reported that men have higher rates of mortality, while women have higher rates of morbidity. The higher rates of mortality for males can be largely explained by the fact that they have higher rates for the chronic diseases which are the leading causes of death. The explanation of why women have higher rates of morbidity, however, remains unanswered. Recent literature suggests three possible explanations: (1) a greater willingness among women as compared with men to report they are ill and/or to react overtly to an illness, (2) the greater ability of women to adopt the sick role due to their lack of obligations, and (3) the possibility that the reported differences reflect real sex differences in illness. This paper evaluates these explanations and provides support for the view that the sex differences in morbidity are real. The data analyzed show that when one controls for marital status, living arrangements, psychiatric symptoms, and nurturant role obligations, the health differences between men and women disappear.

In recent years there has been considerable attention paid to sex differences in morbidity and mortality. Perhaps the most notable aspect of mortality rates during the twentieth century in western society is that there has been a sharp increase in life expectancy, and this increase has been much more marked for women than for men. For example, as Waldron (1976:2) has noted, for the United States in 1920 the life expectancy was 56 years for women and 54 for men, a difference of two years, while by 1970 women's life expectancy was 75, and this was almost eight years longer than that of men. There is at present considerable debate over why men typically die at a much earlier age than women. It has been argued that the different mortality rates of the sexes are primarily due to genetic differences (e.g., Madigan, 1977; Moriyama et al., 1971), to the heavier use of tobacco among men (e.g., Retherford, 1972; 1975; Preston, 1970), and to the masculine sex role which leads to both greater risk taking and to greater experience of occupational stress

(e.g., Conrad, 1962; Waldron, 1976; Russek, 1959; 1964; also see Johnson, 1977). However, in the present paper we are concerned with the causes of sex differences in morbidity and not mortality. We thus are not particularly concerned with causes of sex differences in mortality (an unresolved issue), but we are concerned with the existence of such differences, for they inevitably are a part of the context for viewing sex differences in morbidity (Nathanson, 1977).

In our society sex differences in statistics on morbidity are as consistent as sex differences in mortality, with one basic difference: The pattern is reversed, for adult women have, or at least appear to have, higher rates of physical illness. For example, in the 1972 National Health Survey, adult women had a greater incidence and number of acute conditions, more restricted activity (including both bed disability and the simple nonperformance of one's primary activities), more physician visits, and more discharges from short stay hospitals (Nathanson, 1975:57). These data are consistent with virtually all other recent data on sex differences in morbidity in western industrial societies (Nathanson, 1977; Verbrugge, 1976; 1977; Mechanic, 1976). There is, however, one rate that, while very small, is inconsistent with this pattern. Males are more likely to

have more serious and incapacitating chronic conditions (Nathanson, 1975; 1977; Verbrugge, 1976; 1977).

As Nathanson (1977) notes, "the apparent contrast between excess mortality and female excess morbidity—'women get sick and men die'—was observed in England as early as 1927 (Dunnell and Cartwright, 1927), and [there] has been exciting sporadic comment since that time." In the past few years there have been a number of papers which, noting the sex differences between morbidity and mortality, have attempted to explain the higher rates of morbidity among women. These efforts have concluded that the apparent differences do not reflect real sex differences in illness (see especially Mechanic, 1976; Cole, 1974; Verbrugge, 1976; 1977; and for a much more qualified statement see Nathanson, 1975). This conclusion would seem to follow logically from the sex differences in mortality, where males have the higher rate. However, when one turns to the data on specific types of physical disorders, the apparent contradiction between the sex differences in morbidity and mortality largely disappears. As Verbrugge (1977:285) reports,

when we consider chronic ailments that force a person to restrict activity, a pronounced male excess appears for the majority of conditions. Among them are several leading causes of death. Females have excess morbidity for one important killer (diabetes mellitus) and for such less fatal conditions as mental/nervous conditions, varicose veins, arthritis/rheumatism and genitourinary conditions—causes of much greater morbidity than mortality.

Verbrugge (1977:291) summarizes the data by stating that "most leading causes of death show male excess rates for both morbidity and mortality. The sicker sex does have the higher death rate." It is particularly worth noting that the only major cause of mortality where women have a higher mortality rate is diabetes mellitus, and it is also the only serious (i.e., potentially fatal) chronic condition on which women have a higher morbidity rate than males. In short, "acute illnesses are much more common than chronic ones" and the "leading causes of death do

not tend to be the leading causes of illness" (Verbrugge, 1977:291). This clearly suggests that the sex differences in morbidity are due to relatively minor illnesses. And in fact the study of Hinkle et al. (1960), who looked at employed men and women with comparable backgrounds and jobs, found this to be the case. As has been the case in virtually all studies, they found women to have higher rates of morbidity than men. However, they found that the differences between men and women

could be attributed to a dozen or more symptoms, to wit: the common cold; "grippe"; "sore throat"; acute gastroenteritis; dysmenorrhea; myalgia; "myositis" and symptoms of muscular tension; minor cuts and bruises; headaches; and minor disturbances of work, thought and behavior. (Hinkle et al., 1960:1331)

In summary, the apparent higher rates of morbidity among women are based almost exclusively on higher rates of mild transitory disorders, and the task of determining the cause(s) of the apparent higher rate of morbidity among women must focus on these types of disorders. As is demonstrated below, the conclusion that women do not have higher rates of morbidity than men is based more on supposition than hard evidence and the issue warrants further investigation. Drawing on the work of Nathanson (1975:59) and Verbrugge (1977), we will be concerned with three plausible explanations of the sex differences in morbidity: (1) differences in the general *willingness* of men and women to report they are ill or overtly to react to an illness (i.e., act as if they are ill), (2) the greater ability of women to adopt the sick role due to the characteristics of their role obligations, and (3) the possibility that the differences reflect real sex differences in illness.

PREVIOUS ASSESSMENTS OF THE APPARENT HIGHER MORBIDITY RATE IN WOMEN

The Higher Rate As an Artifact

As noted above, one of the recurring themes in the literature is that women appear to have higher rates of illness because they are more likely to perceive symptoms, are more willing to articulate

them, are more likely to seek professional help and are treated differently from men by the medical profession. For example, Verbrugge (1977:292) states,

Females may have lower thresholds for perceiving discomfort, whether for social (Mechanic, 1965) or biological reasons. Moreover, regardless of a threshold, females may be more willing than males to report a perceived discomfort (Barker, 1953; Chesler, 1972; Enrenreich and English, 1973; Mechanic, 1965; Phillips and Segal, 1969). In addition, females may be socialized (more so than males) to take corrective measures when ill (Chesler, 1972).

Verbrugge goes on to assert that "when illness data are limited to conditions [which receive medical attention or restrict activities], and important sex differential *automatically* enters the data (Mechanic and Newton, 1965)" (emphasis added). Citing Lelanne and Lelanne (1973), Verbrugge (1977:293) also posits a sex bias in the activities of physicians. Clearly implied is that the higher morbidity rates of women do not reflect real rates of illness. And, in fact, in discussing a slight narrowing of the gap in certain indicators of morbidity, Verbrugge (1976:392) argues "females are *choosing* to be less bothered by headaches and earaches, and they are less likely to cut down on activities for these problems" (emphasis added). A generally similar presentation is to be found in Mechanic's (1976) assessment of the reasons for the higher rates of morbidity in women, and an almost identical argument is presented by Dohrenwend and Dohrenwend (1977) regarding why women appear to have higher rates of mental illness.

The basic limitation with the literature cited by Verbrugge, as well as the literature cited by Mechanic, is that while they all present arguments that are similar and/or data that are compatible with the position that the apparent higher rates of women are artifactual, *none* of the works cited presents *evidence* that would come even close to demonstrating this is the case. In short, this body of literature is based on the beliefs of the authors who provide the appearance of empirical support for their assertion by a process of mutual citation.

The only systematic effort to marshal evidence for the higher rates of women being artifactual is in the paper by Verbrugge (1977). It is her position that in an interview situation women are more likely to admit to various forms of ill health than men. The only evidence she presents for the interview effect she postulates is that in the health examination survey where the respondents fill out a questionnaire in private the extent to which men admit to having symptoms of mental illness is smaller than in the Health Interview Survey where the respondents are directly interviewed. There are two fundamental reasons for discounting Verbrugge's interpretation, one dealing with the literature on response bias and one dealing with the items in the two surveys. A review of the evidence by Sudman and Bradburn (1974) on response effects suggests there is no evidence for the interview effect postulated by Verbrugge while there is evidence for the opposite effect; namely, males are more likely than females to underreport undesirable items on a self-administered questionnaire (Sudman and Bradburn, 1974:108-9). Even more critical to Verbrugge's argument is that the two measures used are so different that a comparison is inappropriate. The self-administered measure involves a set of twelve generally minor psychiatric symptoms which the respondent reports as having or not having experienced, whereas the interview survey involves the respondents first stating they have a disability which impairs their performance and then subsequently indicating the disability is due to a mental condition.

As noted, for the vast majority of diseases Verbrugge finds that the sex with the highest morbidity rate is the sex with the highest mortality rate. However, among all the diseases reviewed by Verbrugge there are nine cases where there appears to be a sex reversal and in all cases women have higher morbidity rates and males have higher mortality rates. Although the morbidity rates for some of these disorders are fairly high, in all cases the mortality rates are very low. As Verbrugge notes there are a number of problems with many of these comparisons. For example women report varicose veins

much more frequently than men, whereas men "die of varicose veins" much more frequently than women. However, in the data on mortality due to varicose veins, this disease is grouped with other disorders (probably because mortality due to varicosity is a very rare event and usually confounded with other vascular disorders) and it may well be that men are dying of these other disorders and not of varicose veins and that there is in fact no sex reversal. According to Verbrugge (1977:289) of the nine diseases with an apparent sex reversal there are three diseases where the classification of the disease for morbidity and mortality are very comparable, namely (1) mental/nervous conditions, (2) infective and parasitic diseases, and (3) hypertension without heart disease. We are uncertain how one dies of a mental/nervous condition (neurological conditions and suicide are dealt with elsewhere) and, as Verbrugge (personal communication) notes, with disease where mortality is either very rare (or nonexistent) there is a serious problem of coding errors. The infective and parasitic diseases almost invariably involve acute nonfatal conditions (Verbrugge, 1977:294) and it is our view that the comparison of the sex ratio where a particular combination of a large set of diseases produces high morbidity rates with the sex ratio where the same disorders, in what is probably a very different combination, produce a very low mortality rate is of questionable validity. This leaves hypertension without heart disease, and the evidence here of a sex reversal is substantial. This reversal is based on evidence showing women more likely than men to say they have "high blood pressure" when asked this in the Health Interview Survey (Verbrugge, 1977:293). Since hypertension is a disorder which does not result in symptoms observable to the individual, and since it requires medical verification, unless the individual indicates that a physician has made such a diagnosis, the response is highly suspect. Women are much more likely to feel tense and anxious (Gurin et al., 1960; Gove and Tudor, 1973; Gove, 1978) and thus these higher rates of what Verbrugge calls "hypertension" may simply reflect higher rates of psychological tension. This, how-

ever, is a somewhat speculative interpretation and it is probably best to tentatively treat the data on hypertension as involving a real sex reversal.

In summary, the view that the high rates of morbidity among women are artifactual, while popular has, as a general proposition, very little empirical support. Nevertheless, while it is clearly not proven it has not been disproven and thus remains as a plausible explanation. While we accept the plausibility of the argument, we are inclined to believe it to be incorrect. There are essentially two reasons for our pessimism. First, persons taking this position (particularly Mechanic, 1976) have relied heavily on the article by Phillips and Segal (1969), which argued that the higher rates among women of psychological and psychophysiological symptoms, as measured by the Langner scale, are an artifact of women being more willing to admit to such symptoms. However, with the use of the techniques subsequently developed by Phillips and Clancy (1970; 1972) specifically to test this type of proposition, it has been shown that the Phillips and Segal position is incorrect and that there is no tendency for the rates of women, on the Langner scale or a variety of other scales, to be inflated in the direction of poor mental health (Clancy and Gove, 1974; Gove et al., 1976; Gove and Geerken, 1977a). Second, as the review of the evidence by Gove (1978) shows, in the area of mental illness, after severity of disorder is controlled for, there is no evidence that females are more likely than males to seek professional help or to be processed by medical and mental health professionals in ways that would inflate the rates of women. We would note that the relevance of this evidence is indirect, as it deals with mental illness; however, persons who have argued that the higher rates of morbidity among women for physical illness are artifactual also have drawn primarily on studies dealing with mental illness to support their position. In short, the available evidence, at least by inference, suggests that the higher rates of morbidity reported for women primarily reflect differences in illness behavior or real differences in illness.

Persons who have raised the issue of the

higher rates of morbidity among women being an artifact of the data collection process have pointed to one very real issue. Self-reported morbidity rates tend to be higher than the morbidity rates reported for others by informants. The studies which use a subject both as a respondent providing a self-report and as an informant do tend to have inflated rates for women because the subjects are typically women (Nathanson, 1975; 1977; Verbrugge, 1976; Mechanic, 1976). However, this is not a problem with the majority of studies on morbidity, nor is it an issue with the present study.

The Correspondence between the Women's Role and the Sick Role

As noted, Nathanson (1975:59) indicates that a possible explanation of the higher rates of morbidity among women is that "the sick role is relatively compatible with women's other role responsibilities, and incompatible with those of men." In his overview, Mechanic (1976:37), having a favorable reaction to this proposition, states that "the hypothesis that women's usual role obligations are more consistent with being sick and seeking care is plausibly worthy of more careful consideration. . . ." Mechanic (1976:37-8) then goes on to indicate that the data on the limitation of activities are generally consistent with this formulation. Verbrugge (1977:292) goes further, flatly stating that "females have generally fewer time constraints than males, which allows them to seek medical activity more readily than males." (Also see Verbrugge, 1976.) There is one very serious problem with this proposed explanation of sex differences in morbidity, namely, that it is untested.

We believe that the role obligations of men and women differ and that the role obligations are related to sick role behavior. However, we doubt that the above hypothesis accounts for the higher rates of morbidity among women. As is clearly implied by Mechanic (1976:37) and made very explicit by Verbrugge (1976; 1977), this hypothesis rests on the premise that women, on the average, have fewer fixed obligations and more free time, and that

this is what allows them to adopt sick role behavior. However, the very extensive time budget studies that have recently been completed in the United States and eleven other industrial nations demonstrated that this is not the case (Szalai, 1972). As Szalai (1975:385) concludes in his article summarizing these studies, "wives, employed or not, are still victims of old fashioned attitudes, and work for longer hours than men." Another source of negative evidence is the study by Hinkle et al. (1960), who studied comparable groups of men and women employed in comparable jobs. If the above hypothesis is correct, then since these women presumably have as many role obligations as the men, their morbidity rates should not be higher than those of the men. However, Hinkle et al. (1960) found that the women had more episodes of illness and more disability days than the men.

The Possibility That the Higher Morbidity Rates among Women Reflect Real Differences in Illness

In the recent discussions there has been no attempt to assess seriously the possibility that the statistics on the sex differences in morbidity reflect real differences in illness. This is reasonable because there is no solid data on which such an assessment can be made, and Nathanson (1975; 1977), probably wisely, simply avoids the issue. Mechanic (1976:38), however, asserts in his conclusion that "it is difficult to support the argument that women have more illness than men," and he goes on to indicate that the differences found are due to cultural and social factors. Verbrugge (1976:399) goes further, stating, "we suspect that males are physically sicker from both acute and chronic conditions, but that social and psychological factors enhance female reports to such an extent that a female excess appears overall."

The little effort that has been directed at assessing the relationship of morbidity to actual illness has focused exclusively on the relationship of mental illness to morbidity. Although we are primarily concerned with physical illness and morbid-

ity, it is worthwhile looking at these evaluations. Gove and Tudor (1973) found that when mental illness is defined as a disorder involving distress and/or mental disorganization, in modern western industrial societies, women on *all* indicators uniformly have higher rates of mental illness. This article is controversial and has received considerable scrutiny; however, from the subsequent research and debate it has become clear that when mental illness is defined in this manner women consistently have higher rates as is suggested by the fact that Gove and Tudor's strongest critics, the Dohrenwends, concur that this relationship exists (Dohrenwend and Dohrenwend, 1976; 1977). However, Dohrenwend and Dohrenwend strongly believe that the definition of mental illness should be greatly broadened to include a variety of forms of deviant behaviors which involve aggressive asocial and antisocial acts and which could be classified as forms of the personality disorders. Mechanic strongly supports the position by Dohrenwend and Dohrenwend. In reference to the study by Gove and Tudor (1973), Mechanic (1976:33) states that "such analyses are useless or worse" and asserts that this is because they "eliminate from consideration such entities as alcoholism, personality disorders, or acting out behaviors." This statement by Mechanic is, in fact, the only statement in the literature we have reviewed which attempts to justify the conclusion that the apparent higher rates of *physical illness* among women do not reflect real differences in illness.¹

¹ It is ironic that they are attacking Gove for being unaccepting of and directly abusing the psychiatric perspective, while other sociologists have roundly attacked Gove for being overly accepting of the psychiatric perspective. For example, Scheff (1975:256) asserts that Gove's "imagination is so captured by the psychiatric perspective that his argument turns out to be circular" and later (p. 256) refers to "Gove's exclusive commitment to the psychiatric perspective." The reader who feels that this suggests there may be some inconsistency in Gove's position is referred to Gove (1976) where he discusses this issue. At a time when social scientists have become very critical of the medical profession in general and psychiatry in particular for inappropriately attempting to "medicalize" a number of forms of deviant behavior, including those listed by Mechanic, we find it surprising that such prominent social scientists

Summary of the Literature

It has been proposed that the apparent higher rates of morbidity among women are not due to real differences in illness but to women being more sensitive to their symptoms, more willing to articulate them and more willing to seek professional help. It has also been proposed that because women have more free time and fewer fixed role obligations they are more likely than men to be in a position where they can adopt the sick role and manifest illness behavior. Much of the literature on women and women's roles is consistent with both these formulations and, given the fact that the disorders under consideration are mild and difficult to measure independently, both of these hypotheses seem plausible. However, as we have noted, these hypotheses have not been tested and there are reasons for suspecting that they do not account for the higher rates of morbidity among women. The alternative hypothesis, of course, is that the sex differences in morbidity reflect real differences in illness. This alternative hypothesis has been viewed as improbable; however, it also is untested. In the remainder of the paper we will present evidence to test the hypothesis that the apparent higher rates of morbidity are due to real differences in occurrence of physical disorder.

THE STUDY

Conceptualization

Historically, the medical model has been concerned with physical agents or causes of physical disorders. A small residual category of psychosomatic disorders which were presumed to be caused by psychological distress was considered irrelevant to this model. However, in the past two decades it has become very clear that psychological factors, particularly poor mental health, play an important etiological role in a wide range of disorders not traditionally labeled psychosomatic (e.g., Thurlow, 1967; Moss, 1973;

as David Mechanic and Bruce Dohrenwend and Barbara Dohrenwend would be so certain of their assumption that these "disorders" should be treated as mental illness.

Dohrenwend and Dohrenwend, 1974; Dodge and Martin, 1970; Gove, 1973; Little, 1976; Renne, 1971; Markush et al., 1977). Furthermore, psychological distress both as an etiological factor and as a factor affecting the treatment process is belatedly becoming incorporated into the medical model where it is treated as one of the critical variables (e.g., Engle, 1977).

As noted, the higher rates of morbidity in women are primarily attributable to the manifestation of higher rates of mild forms of physical illness. In general, most of these illnesses would seem to be prime candidates for the categories of physical disorders that are reactive to psychological distress. Hinkle et al. (1960:1333), in fact, concluded that the sex differences in morbidity are largely due to physical illnesses that are a consequence of psychological distress. Furthermore, the items in such widely used mental health scales as the Langner (1962) scale and the HOS scale (McMillan, 1957), were selected solely on the basis of the items' ability to distinguish between persons in good and poor mental health, include a variety of psychophysiological and organic symptoms. This fact suggests that poor mental health is related to the manifestation of a variety of symptoms of physical disorder.

In summary, there are substantial theoretical and empirical grounds for assuming that poor mental health is causally linked to mild forms of physical disorder. *One of the hypotheses guiding the present study is that poor mental health is causally linked to poor physical health and this partially explains the higher rate of morbidity among women.*

The second hypothesis guiding the study is that certain types of role obligations interfere with one's ability to care properly for oneself and thereby produce minor forms of disability, and that such obligations occur more frequently among women and therefore partially account for their higher rate of morbidity. In particular, we are assuming that one of the characteristics of the female's role that distinguishes it from the male's role is that women are obligated to care for others and that such care may interfere with their ability to care for themselves. In particu-

lar, we assume that women, as compared with men, typically have more role obligations that require constant ongoing activities vis-à-vis their spouse, children and others (such as parents) living in the home, and that these obligations can interfere with self-care and have a negative effect on one's health.

Our basic premise is that sex differences in morbidity are due to sex differences in the characteristics of role obligation and mental health, and that if we can control for these differences the sex differences in morbidity will largely disappear. The controls can involve both statistical controls and the selection of certain types of populations. An example of the first case, where statistical controls are of key importance, are married men and women. It is our hypothesis that married women, as compared with married men, have many role obligations that interfere with their ability to take care of themselves, and we know that married women tend to be in poorer mental health (e.g., Gove, 1972; Gove and Geerken, 1977b; Pearlin, 1975; Radloff, 1975). The main instance where we would anticipate few differences between men and women in their morbidity rate is among persons who live alone. For example, men and women who live alone are similar in that they have no obligations to persons living with them (as there are none) and, following Gove and Tudor (1973), one might anticipate men and women who live alone to be in relatively comparable mental health. If we find, as have virtually all other studies, that women have higher rates of morbidity but that these differences disappear when our controls are introduced, then this would virtually eliminate the possibility that the apparent higher rates of morbidity are artifactual or due to greater ability of women to adopt the sick role because they lack obligations toward others.

The data for our analysis was drawn from a survey conducted in Chicago which focused on the effect of household overcrowding on behavior. The sample was comprised of randomly selected adults residing in randomly sampled households in census tracts that were selected to maximize variation between

socioeconomic variables and household crowding. If no one was contacted on the first attempt, three additional calls were made for a total of four contact attempts. We had a 68.1% response rate at the time of the screening interview and a 89.1% response rate for the full interview² (for details of the sampling and methodology, see Gove et al., 1979). We know of no theoretical or pragmatic reason why this method of selection would affect the nature of the observed relationships; nevertheless, one should not generalize the specific values found to any population other than the specific census tracts selected. A second limitation of the sample is that considerably more women (65.8%) than men (34.2%) were interviewed. This over sampling of women appears to be a characteristic of household surveys. For example the other recent survey in Chicago which attempted to preselect the sex of respondent to equalize their number (Ilfeld, 1976) and the overcrowding study by Booth (1976) which attempted to preselect equal numbers of men and women yield both heavily oversampled women. Similarly, the recent national survey by Campbell et al. (1976) also substantially oversampled women. Since we treat men and women separately in our analysis, the undersampling of men should not affect the pattern of the relationships. As we see it, these are the only serious limitations of the sample. We have shown in Gove et al. (1979) that except for

sex, on all demographic characteristics (including levels of household crowding) the characteristics of the sample are virtually identical to those of the population of Chicago and generally similar to the characteristics of the population of the United States.³

Independent Variables

One of the issues we were concerned with was whether or not crowding had a negative effect on physical health. In the interview the respondents were asked five questions, dealing with different facets of the structure of their life, which we felt would affect their physical health. The questions were: (1) Do you think you get enough sleep? (2) If someone else at home is sick with the bug, do you often seem to catch it? (3) When you are *really* sick, are you almost always able to get a good rest? (4) Even when you are really sick, are there a number of chores you just have to do? And (5) When you are really sick is there someone to help take care of you? It is our hypothesis that in fulfilling their socially defined role obligations women, as compared with men, tend to perform nurturant tasks. Thus, when they are in situations where there are others to be taken care of, it will be women and not men who will tend not to get enough sleep, to be more likely to catch "bugs," not to get a good rest when sick, to "have" to perform chores when sick, and not to be as well cared for. The only important exception to this hypothesis is the males who by their situation are forced to play a nurturant role as, for example, males solely responsible for the care of young children.

As noted above, it is also our hypothesis that poor mental health is causally related to poor physical health and that, as females tend to be in poorer mental health than males, this is one of the causes of the higher rate of poor physical health among females. As a measure of poor mental health the respondent was asked if he or

² By historical standards this refusal rate is high. However, it compares quite well with the two most comparable studies, namely, one done with the same general population, in this case the Standard Metropolitan Statistical Area of Chicago in 1972 (Ilfeld, 1976) and the other being the only major survey on the effect of overcrowding on behavior conducted in a city in North America, in this case Toronto (Booth, 1976). As noted, we had a refusal rate of 31.9% on the screening interviews and a 10.9% refusal rate after the screening interview. In the other Chicago study the refusal rate for the screening interviews is presented as 31%, but they present no information on refusal rate after the respondent was selected. In the Toronto study they screened 17,000 households to select 862 households for interviewing. No refusal rate is presented for the screening interviews. Among the households selected after the screening interviews, they experience a 35.3% refusal rate per household, and as they were trying to interview both husbands and wives but were often unsuccessful, they had an overall respondent refusal rate of 50.3%.

³ Although we have an undersampling of males, we would note that the demographic characteristics of the males in our sample are virtually identical to the demographic characteristics of males in Chicago in 1970.

she had experienced the following symptoms often, sometimes or never during the past few weeks: (1) thought that people were saying all kinds of things behind your back; (2) bothered by special fears; (3) were so blue or depressed that it interfered with your daily activities; (4) thought that it was safer to trust nobody; (5) bothered by nervousness, such as being irritable, fidgety or tense; (6) were in low spirits; (7) bothered by special thoughts; (8) were so restless that you couldn't sit long in a chair; (9) felt as if nothing turned out the way you wanted it to; (10) felt somewhat apart or alone even among friends; (11) felt that personal worries were getting you down physically, that is, making you physically ill; and (12) felt that nothing was worthwhile anymore. For information supporting the reliability and validity of these items the reader is referred to Gove and Geerken (1977a) and Brocki and Gove (1978). For present purposes we would simply emphasize two points. First, unlike most instruments in surveys to measure mental health (e.g., the Langner [1962] scale, the HOS scale [McMillan, 1957] and the Gurin et al. [1960] scale), this scale does not contain items that can be interpreted as physical symptoms of organic disorders. Thus, if there is a relationship between this measure of mental health and physical health it cannot be attributed to overlapping items. Second, the relationship of scores on this measure of mental health and gender is not affected by response bias (Gove and Geerken, 1977a).

Dependent Variables

Most surveys, such as the National Health Survey, which have been used in the attempt to determine whether or not there are sex differences in physical illness, have attempted to measure a person's actual physical health and whether or not physical illness has functionally impaired his or her role performance (e.g., Nathanson, 1975; 1977; Verbrugge, 1976; 1977; Mechanic, 1976). In the present study we have indices of the respondents' general physical health and their role functioning. As the present study did not focus on physical illness, detailed information

on actual physical disorders was not obtained. Instead the respondents were asked this general question: Would you say that your overall health is (1) excellent; (2) good; (3) fair; or (4) poor? Reliance on such a general question as this has certain limitations, although it is obviously desirable to use an overall indicator of physical health. The study by Reynolds et al. (1974) indicates that responses to this general question are strongly related to a person's actual physical health as indicated by a detailed examination of indicators of physical illness. Furthermore, Singer et al. (1976:519) in their Midtown Manhattan Restudy found that a respondent's answer to this question was a strong predictor of the probability of dying in the next twenty years. The general nature of this question is in many respects a positive attribute for the purposes of this study. As the evidence in Sudman and Bradburn (1974) shows, general questions such as this tend to be particularly reactive to response bias. Furthermore, this question should be reactive to the presumed greater ability of women to adopt the sick role and hence define themselves in poor physical health. Thus by using this question we are weighing the results against our hypothesis and in favor of the counterhypothesis.

As an indication of the extent to which physical illness affected the respondent during the past two weeks, the respondents were asked the following question: (1) During the *past two weeks*, did you have to stay in bed either all or part of the day because you were not feeling well? and [if yes], how many days during the past two weeks (number of days)? (2) During the *past two weeks* (and not counting the days you stayed in bed) was there any time you were unable to do the things you *normally* do because you did not feel well? and [if yes] how many days during the *past two weeks* did this happen (number of days)? (3) In addition to what you have already told me, was there any time during the past two weeks when you did *not* feel well or when you noticed something was wrong with your health? and [if yes] how many days during the past few weeks did this happen (number of days)? In our analysis we have looked at (1) the occur-

rence of any illness (i.e., not feeling well), (2) the occurrence of functional impairment (i.e., not doing things), (3) spending any time in bed due to sickness; and (4) an index that combined indicators of the different types of impairment that were weighted for their severity and multiplied by the number of days of their occurrence. In our analysis of these different indicators, the results and the conclusions were virtually interchangeable. In our presentation we will use as our indicator whether or not during the past two weeks the respondents did not perform various activities because they were not feeling well. This indicator is very similar to some of the indicators used in the Health Interview Surveys. Like the indicator of general physical health, this measure also is potentially highly reactive to processes postulated by the two hypotheses which are the main alternatives to the one under investigation.

Control Variables

In our analysis we will be controlling for and looking at the comparative effects of the following demographic variables: (1) age, (2) family income, (3) respondents' education, and (4) race.⁴

Mode of Analysis

In many ways our analysis and presentation is extremely simple and straightforward, relying exclusively on percentages, means and the proportion (%) of total variance explained. Nevertheless, as our analysis utilizes the dummy variable regression program, Multiple Classification Analysis, developed by Andrews et al. (1969) and both relies on the clarification of a meaning of a measure of association presented in that program and develops a new measure of association, some interpretive comments are in order.

In essence, Multiple Classification

Analysis is a dummy variable regression analysis which presents mean scores for the various categories of an independent variable both before and after adjusting for the effects of a set of control variables. In the instance where the dependent variable is dichotomized, the mean is of course a percent. A very straightforward way of looking at the unadjusted and adjusted means is to view them as unstandardized and standardized rates. Thus, for example, in looking at health differences in men and women with and without adjusting (controlling) for age differences between the sexes, the unadjusted mean health scores would be those that actually occur in the sample or population, and adjusted means would be the differences between the sexes that would occur if the rates for men and women had been age standardized using the overall values of the whole sample or population. In our analysis we will be looking at the sex differences on our two indicators of health prior to controlling for the demographic variables noted above and after controlling for these variables; this analysis will thus indicate the degree to which sex differences can be accounted for by differences in our demographic controls. We will then look at the sex differences in health with and without adjusting (controlling) for the role variables and psychiatric symptoms. If our hypotheses are correct, then when men and women are in situations where they differ on an index of role characteristics and mental health, women should be in poorer physical health and, after adjusting for these characteristics (i.e., after standardizing the rates for men and women so that the sexes are "comparable" on their role and mental health characteristics), then the sex differences in physical health should disappear.

So far we have discussed the interpretation of the means and percentages to be presented. We will also be using PRE (Proportional Reduction in Error) measures of association (Costner, 1965) throughout the analysis. The MCA program presents Eta and Eta². Eta², of course, presents the proportion of the total variance in the dependent variable that is explained by the independent variable at

⁴ Age was categorized into six categories (18-25, 25-35, 35-45, 45-55, 55-65, and 65+), income into eight categories (less than \$2,000; \$2,000-\$3,999; \$4,000-\$5,999; \$6,000-\$7,999; \$8,000-\$11,999; \$12,000-\$19,999; \$20,000-\$29,999; \$30,000+), education into six (0-7, 8, 9-11, 12, 13-15, 16+), and race was categorized as white and nonwhite.

the zero-order level. Eta^2 is directly analogous to r^2 except that the independent variable is categoric and not linear. The MCA program also presents Beta and Beta^2 for the independent variables as an indicator of the strength of association after the mean scores have been adjusted. Although Andrews et al. (1969) present their Beta and Beta^2 as measures of association, they specifically note that they are unable to provide any clear interpretation of what the measure means. However, an analysis of how Beta^2 is computed shows that it is not only a PRE measure of association, but it is also directly analogous to Eta^2 , and that a comparison of Eta^2 and Beta^2 shows precisely the effect of introducing a set of control variables on an independent variable and a dependent variable.⁵ We will also be using an overall indicator of the total variance explained by our set of independent and control variables, which we will denote as $M\eta^2$ and refer to as multiple Eta^2 . $M\eta^2$ is produced by simply dividing the total explained sum of squares by the total sum of squares. This measure is directly analogous to multiple R^2 except for the fact that the set of independent and control variables are treated as categoric and not linear.⁶

THE DATA

The data associated with nurturant role attributes and psychiatric symptoms are

⁵ To use the example of sex differences in health before and after adjusting (controlling) for age, Eta^2 would be the percentage of the total variance in health that at the zero-order level can be attributed to sex differences, while Beta^2 would be the percentage of the total variance in health that can be attributed to sex differences after the rates of men and women have been age standardized. In this example, if $\text{Eta}^2 = .020$ and $\text{Beta}^2 = .020$, we know that gender accounts for 2% of the total variance in our indicator of health and that this difference between men and women cannot be accounted for by age differences between men and women. In contrast, if $\text{Eta}^2 = .020$ and $\text{Beta}^2 = .010$ then we know that at the zero-order level gender accounts for 2% of the variance in health, but that one-half of the difference between the sexes is due to their age difference and that only 1% of the total variance should actually be attributed to sex.

⁶ The reader should be aware that $M\eta^2$ is not the adjusted R^2 presented in the MCA program, and that the adjusted R^2 presented is not a PRE measure and that it has no clear substantive interpretation.

presented in Table 1. Looking first at all married respondents, we see that in every case women are higher on those attributes which we have postulated are associated with poor physical health, and that, in all cases except for getting enough sleep, the differences are statistically significant. The comparison of married men and women with and without children shows that the presence of children has much more of an impact on women than men, and that women with children fare considerably more poorly than comparable males. However, even among those without children, married women have higher rates of those attributes presumed to be associated with poor physical health. In short, a comparison of married men and women shows that, on the nurturant role attributes (which are presumed to be associated with poor physical health) and on our measure of psychiatric symptoms, married women have higher values than married men. Thus, according to our hypothesis, married women should be in poorer physical health, but this difference should largely disappear when we control for the respondent's nurturant role attributes and mental health.

As anticipated, males and females who live alone are virtually identical on their nurturant role attributes (with the one exception that women are more likely to be cared for when really sick) and mental health. Thus, we would predict at most minor sex differences in physical health among men and women who live alone, at least after demographic controls, and that any sex differences that did occur would be virtually unaffected by controlling for the respondents' role attributes and mental health.

Looking at all formerly married men and women living with others shows a pattern generally similar to that found with married men and women. On the first four indicators of nurturant role attributes married women and formerly married women are very similar, while in comparison formerly married women are less likely to have someone to take care of them when they are sick and they tend to be in poorer mental health. A comparison of formerly married men shows a similar pattern, although the rates are less stable due to the

low number of men. There are only three formerly married men with young children, and so it is impossible to draw any firm conclusions about the effect of children on men in this situation. However, the fact that they have higher rates of psychiatric symptoms than any other males and fare poorly on a number of the role attribute items suggests that they find the care of children problematic. Children have a very marked effect on the role attributes and mental health of divorced women and a parallel but much more modest effect on widowed women. The more modest effect of children on widowed women may be due to their children generally being older than the ones living with divorced women. Following our hypothesis, these data would suggest that formerly married women living with others would be in poorer physical health than comparable formerly married men, but that this difference would largely disappear when we control for the respondents' nurturant role attributes and mental health.

The pattern with never married men and women who live with others is generally similar to the pattern with married men and women and formerly married men and women, although it is not quite as sharp on the role characteristics. This lack of sharpness on the role characteristics is consistent with the view that never married women, on the average, would not have assumed the degree of nurturant responsibilities associated with marriage and/or children. As before, these data lead to the prediction that never married women would be in somewhat poorer physical health than never married men, but that much of this difference would disappear when we control on the respondent's nurturant role attributes and mental health.

In our analysis we looked at the effect that controlling for the demographic characteristics of the respondent had on the relationships associated with the nurturant role attributes and psychiatric symptoms. For the nurturant role attributes it was obvious that controlling on the demographic characteristics has no effect on the rates. An analysis of psychiatric symptom scores of respondents who are mar-

ried or living alone shows that demographic controls also have no effect on the sex differences in the mental health scores. However, controlling for the demographic characteristics among formerly married and never married respondents who live with others produces a marked decline in the extent to which women have higher psychiatric symptom scores. It appears that most of the effect of the controls in these two cases can be attributed to the fact that women in these categories tend to live under much more trying socioeconomic circumstances, and that these circumstances play a substantial role in their high psychiatric symptoms scores.

Table 2 presents first the total variance in the dependent variables that is explained and second the percent of that variance that is uniquely explained by (1) the demographic controls and (2) the independent health variables, as well as (3) the percent of the total variance that is collinear with both the demographic and independent health variables. For the independent health variables the table also presents the percent of the total explained variance that is uniquely explained by (1) the role variables, (2) psychiatric symptoms as well as (3) the percent of explained variance that is collinear between the role variables and psychiatric symptoms. Table 3 shows that (for survey data) our independent and control variables are generally explaining a considerable proportion of the total variance in the dependent variables. With regard to the respondents' evaluation of their general physical health, among those who are married or living alone the demographic controls are more powerful than the independent health variables, although the effect of the independent health variables is very substantial. In contrast, among formerly married persons living with others and never married persons living with others, the independent health variables are more important than the demographic controls. Turning to functional impairment, one sees that in every case the independent health variables are more important than the demographic controls. In general the psychiatric symptom measure is a more powerful predictor than the role variables,

Table 2. Apportioning the Variance Explained in the Respondent's General Physical Health and Functional Impairment

	Married		Living Alone		All Formerly Married Living with Others		Never Married Living with Others	
	General Health	Functional Impairment	General Health	Functional Impairment	General Health	Functional Impairment	General Health	Functional Impairment

2a. % uniquely by role variables	(10.2)	(30.5)	(5.5)	(5.4)	(9.4)	(7.0)	(4.7)	(15.4)
2b. % uniquely by psychiatric symptoms	(21.6)	(19.5)	(20.7)	(50.8)	(31.4)	(44.9)	(37.2)	(19.5)
2c. % collinear between role and psychiatric variables	(9.3)	(18.3)	(8.9)	(-2.2)	(11.6)	(14.8)	(14.5)	(19.5)
B. % Variance Collinear between Demographic and Independent Health Variables	8.5	12.2	7.9	28.1	4.4	1.6	10.5	6.8

and this is particularly true for persons living alone—who of course are in situations where there is very little variation in the nurturant role variables. The relative effect of the nurturant role variables is greatest among the married, the category of respondents where one anticipates the greatest nurturant demands. Overall, very little of the variance is collinear between the independent health variables and the demographic control variables. Taken as a whole, the data presented in Table 2 strongly suggest that both nurturant role characteristics and mental health play a significant role in the respondents' evaluation of their overall physical health and in the occurrence of functional impairment.

An analysis of the effect of the nurturant role attributes and psychiatric symptoms on the respondents' (1) general physical health and (2) functional impairment for our four categories of respondents shows that all of the relationships are in the predicted direction and almost all of the relationships are statistically signifi-

cant. An analysis of the role characteristics shows that not enough sleep and, particularly, an inability to get a good rest when sick are the variables most strongly related to poor physical health and functional impairment. This suggests that being physically run down, presumably because of performing one's role requirements, is a significant cause of poor physical health. The relationship between psychiatric symptoms and both general health and functional impairment is considerably stronger than that found with any of the role items. In part this is due to the greater number of categories in the psychiatric symptom scale. However, it is probably also due to the nature of the instrument. Both indicators of the respondent's physical health deal with the respondent's physical health at the present time. The measure of psychiatric symptoms also deals with the respondent's present mental state, and thus there is a direct correspondence in time with the measure of physical health and mental health. In

Table 3. Sex Differences in the Respondent's Evaluation of their General Physical Health: An Analysis of the Consequences of Controlling for the Effects of Demographic Variables, Nurturant Role Characteristics and Mental Health among Different Categories of Respondents

contrast, four of the five variables dealing with the respondents' role attributes deal specifically with problems that arise when the respondent is already not feeling well. Thus, their major effect may be to exacerbate an illness once it develops and the items may be more peripherally related to the respondent's average physical health. It is thus possible that poor mental health might be more strongly associated with a person's average physical health, while the nurturant role attributes which we are measuring may primarily have a strong impact on a minor physical disorder once it arises and play a very substantial role in the development of such a disorder, for example, playing a key role in determining whether a physical disorder becomes so

serious that medical treatment is desirable.

Table 3 presents the respondents' overall evaluation of their physical health by sex, (a) without controls, and with controls for (b) demographic variables, (c) demographic variables and role characteristics, (d) demographic variables and mental health, and (e) demographic variables, role characteristics and mental health. With regard to our hypothesis, this is the key analysis for our indicator of the respondents' general physical health. First, let us look at the relationships for the married. The data show that there is a statistically significant relationship in the predicted direction between sex and physical health, and that this relationship is not

affected by demographic controls. When the respondent's nurturant role characteristics or the respondent's mental health is added to the demographic variables as a control, the sex differences are markedly reduced. A comparison of the sex differences in physical health, first with demographic controls and then with demographic controls combined with the respondent's role characteristics and mental health, shows not only (1) that the sex differences in physical health are no longer statistically significant, and that the explained variance attributed to sex has been reduced by 75%, but also (2) that the relationship is no longer monotonic, with men being more likely than average to be in both "excellent" and particularly "poor" physical health, while women have relatively high rates of "good" and "fair" physical health. These data thus fit perfectly with our hypothesis that sex differences in physical health are due to sex differences in nurturant role demands and mental health. It is particularly important to note that the study by Gove and Geerken (1977b), which uses this same data, is able to show fairly convincingly that poorer mental health among married women is due to the characteristics of their role. In short, it appears that the higher rates of poor mental health among married women, which partially account for their higher rates of poor physical health, can in turn be attributed to the characteristics of their role.

Among respondents living alone, on the average, women are in poorer physical health. However, after demographic controls this relationship diminishes sharply and no longer even approaches statistical significance. Furthermore, adding controls for the role variables and/or mental health has no effect on the sex differences in physical health. These results are what would be predicted by our hypothesis. Nevertheless, we would note that in all comparisons after controls women do tend to be in slightly poorer physical health, which suggests that among these respondents there may be some small residual determinant of sex differences in physical health which has not been captured by our controls.

Among formerly married respondents

living with others, the sex differences in physical health are not statistically significant. Nevertheless, before and after demographic controls women do tend to be in poorer physical health than men and, as measured by Beta², this sex difference is as strong as that found among married men and women. The prime reason that the relationship between married men and women is statistically significant, while among the formerly married it is not, is due to the much smaller number of cases of formerly married. As occurred with the married, adding either role attributes or mental health to the demographic variables as controls discernibly reduces the sex differences in physical health with demographic controls. When both the respondents' role characteristics and mental health are added to the demographic variables or controls, the data show that sex, as a predictor of physical health, becomes a trivial variable (see the Betas), and that the relationship of sex to physical health is no longer even monotonic. In short, these data also fit our hypothesis.

Never married women living with others tend to be in poorer physical health than comparable men, and this relationship is statistically significant. However, after the demographic characteristics of the respondent are controlled for, this relationship is reduced to statistical insignificance. Nevertheless, the *n* is relatively small, women do still tend to be in poorer physical health and, as indicated by the Beta², the strength of this relationship is not trivial. Controlling for the role characteristics of the respondent as well as the demographic variables discernibly reduces the sex differences in physical health and the relationship is clearly no longer monotonic. Nevertheless, overall these women do still tend to be in poorer physical health than their male counterparts. Among these respondents the effect of mental health on sex differences in physical health is slight. These data could be interpreted in a variety of ways, depending upon one's inclinations. One interpretation is that after demographic controls there are no sex differences in physical health. Another is that after demographic controls there are some differences in physical health, and these are discernibly

who live alone report, they also report slightly more functional impairment.

Among the formerly married respondents who live with others there are no statistically significant sex differences in functional impairment either with or without controls. Nevertheless, women in this category report more functional impairment than men do, and this relationship remains after demographic controls. However, if in addition to the demographic variables one also controls for either nurturant role characteristics or mental health, the functional impairment of men surpasses that of women. Furthermore, if one controls for both nurturant role characteristics and mental health, the proportion of men who are functionally impaired surpasses that of women by 6.9%. In summary, these data are also consistent with our hypothesis.

None of the relationships with never married respondents who live alone are statistically significant. However, it is again the case that women in this category report higher rates of functional impairment than men. Demographic controls reduce the extent to which women report higher rates of functional impairment, but after such controls the rate for women is still slightly higher than that for men. Controlling for the effects of either nurturant role characteristics or mental health on the reports of functional impairment shows they both have modest effects. And in fact, when both are controlled for simultaneously, the rate of functional impairment of men very slightly surpasses that of women. Thus, like the rest of the data on functional impairment, these data also support our hypothesis.

CONCLUSION

From the literature on sex differences in morbidity and mortality it is clear that the higher rates of morbidity among women as compared with men are due to higher rates of relatively mild forms of physical illness. We have hypothesized that the sex differences in such rates are largely due to the nurturant role demands confronting women, which prevent them from taking good care of themselves, and their rela-

tively poor mental health which, based on the literature, also was assumed to be largely associated with the women's role. Following from this analysis, it was postulated that men and women who live alone would be in relatively similar physical health. We looked at two different indicators of physical illness, the respondents' overall evaluation of their physical health and the occurrence of a functional impairment in the past two weeks across the following categories of respondents: the married, persons living alone, the formerly married living with others, and the never married living with others. In our analysis we looked at the effects of nurturant role demands and mental health on sex differences on physical illness. In seven of the eight comparisons the results provided strong support for our hypothesis. In the remaining comparison, the respondents' evaluation of their general health among those who were never married and living with others, the results are probably best viewed as equivocal, neither clearly supporting nor contradicting our hypothesis. We take the overall results as indicating that the sex differences in physical health largely reflect real differences in physical health, and that this difference can be primarily attributed to women confronting more nurturant role demands and generally being in poorer mental health.

A hypothesis that was not a focus of the present study is that sex differences in physical health can be partially attributed to sex differences on demographic variables which are related to characteristics of their life experiences. As we have seen with the measures of the respondents' general health, most of the sex differences among respondents who live alone and, to a somewhat lesser extent, among never married respondents living with others can be attributed to sex differences on the demographic variables. To a much lesser extent this is also true with regard to sex differences in functional impairment among never married respondents living with others. These differences appear to be largely due to socioeconomic differences, particularly income. Women on their own simply do not fare as well, on the average, in the economic market. These results

demonstrate the importance of looking at the effects of demographic characteristics when investigating the determinants of sex differences in physical health.

In the introductory section of the paper we discussed two alternative explanations of the higher rates of physical illness among women, namely, (1) that women are more willing to articulate and take action on mild forms of physical illness, and (2) because of their lack of role demands, women can more readily adopt the sick role. In our analysis we found no evidence for the latter hypothesis and, in fact, it appears that it is an excess of role demands that partially accounts for why women have higher rates of physical illness. The evidence with regard to the first hypothesis is less clear. Among respondents living alone, women with and without controls appear to have slightly poorer physical health and slightly more functional impairment, and never married women who live alone also appear to be in slightly poorer physical health after controls. These results could be interpreted as indicating that some of the apparent higher rates of physical illness among women are partially due to their greater willingness to articulate and act upon their symptoms. While we find this is a plausible interpretation of the data, we are inclined to think it is not the correct interpretation. First, after controls, formerly married men who live with others have higher rates of functional impairment than comparable women and, to a much lesser extent, the same pattern holds among never married respondents who live with others. These data thus run directly counter to the alternative hypothesis. Second, this same explanation has been posed as an explanation of why women appear to have higher rates of mental illness, and it has been fairly convincingly demonstrated in the area of mental illness that this is not a tenable explanation (e.g., Clancy and Gove, 1974; Gove et al., 1976; Gove and Geerken, 1977a; Gove, 1978).

From all the research on sex differences in physical health it is clear that the higher rates of women are found almost exclusively among the mild forms of physical illness. The data presented in this paper

suggest that the higher rates of women among mild forms of physical illness are largely real. Although, as noted above, there are certain limitations with the data in this study, overall we feel the evidence for this conclusion is quite compelling although replication is clearly desirable. This conclusion runs directly counter to assertions made by Verbrugge (1976; 1977) and Mechanic (1976), but these were assertions lacking any clear empirical support. It is our belief that these assertions are based on the recognition that (1) women do complain more than men about physical problems, and (2) the belief that this is due to it being normatively more appropriate for women to do so. Our analysis suggests that the basis for the complaints is largely real. Assuming that we are correct, this does not necessarily mean that the stigmatization for men and women for verbalizing physical complaints is equal. It is possible that the high rates of illness among women lead to high rates of complaining and this high rate of complaining in turn leads to the social acceptance of the fact that it is more "normal" for women to complain than men. According to this reasoning, the social acceptance of women complaining is not a major cause of their complaining. Instead, the recognition that women complain about their physical problems more than men is an adaptation to the fact that women have more to complain about.

The reader should be aware that although we find virtually no effects of interview behavior or sick role behavior there is nothing in our analysis that suggests such effects do not exist. There is, of course, considerable evidence that such effects do exist. What our analysis suggests is that these effects are unrelated to the sex of the respondent and thus in our analysis these effects show up as random noise. This pattern precisely parallels the pattern found with mental health where there are strong respondent/interviewer relationships to scores on mental health scales, but these relationships are unrelated to sex and thus they do not affect the comparison of men and women on measures of mental health (Clancy and Gove, 1974; Gove et al., 1976; Gove and Geerken, 1977a).

DECISION MAKING AND NON-DECISION MAKING IN CITIES: SOME IMPLICATIONS FOR COMMUNITY STRUCTURAL RESEARCH*

RICHARD A. SMITH

Florida State University

American Sociological Review 1979, Vol. 44 (February):147-161

The literature relating community structural characteristics to policy outputs generally has failed to account for communities not considering an issue as a third type of outcome beyond rejection and adoption. It is argued that nonconsidering communities are likely to be very different from both nonadopters which have considered a policy and have subsequently decided to reject it and from those adopting a particular policy. These types should be separated in research on community structure and community outputs. The current research distinguishes between these three outcome types for fluoridation programs and relates these distinctions to the three important community structural characteristics of structural differentiation, community integration and the centralization of authority within municipal governments. The results of the analysis support the hypotheses, showing that both affinities and disaffinities exist between the communities classified by the three-part outcome typology. Rejecters and adopters are shown to be similar in terms of levels of structural differentiation, and can be distinguished from the less differentiated, nonconsidering communities. Conversely, both nonconsiderers and adopters tend to be more highly integrated and exhibit a greater centralization of authority than rejecters.

INTRODUCTION

The study of the relationships between community structural characteristics and policy outcomes has tended to concentrate on a relatively simple conceptualization of outcome states. Communities are usually classified as having adopted or not adopted a particular policy, with the attempt then being made to relate these actions to important structural characteristics of communities that are hypothesized to affect the probability of these outcomes. Common variations to this adopt vs. nonadopt dichotomy have included the use of variables measuring the extent of adoption (as in level of funding or monies spent) or the speed of adoption (as with the amount of time passed from a given point of program availability to adoption). These variations, however, maintain the common two-part distinction between adopting and nonadopting communities.

We can question whether this simple nominal formulation of outcome states or the more complex variations adequately represent the total set of outcomes that a

community may display on any given issue or policy. One potentially important omission has been the recognition of communities that have never publicly considered an issue or policy. Communities falling into this third category clearly have taken a different action (or nonaction) from those communities having considered an issue and subsequently having decided to reject or adopt it. By employing only the adopt vs. nonadopt distinction, current research efforts, invariably have included this third type of community in the category of those rejecting a policy, thus confusing two potentially different types.

If a reasonable basis exists for assuming that the community structural characteristics associated with nonconsideration vs. rejection of a policy are the same, then treating the two types as one will result only in a loss of theoretical specificity, with no differences in empirical outcomes. It can be argued, however, that the structural characteristics likely to be associated with nonconsideration vs. rejection, and indeed, between the three types of outcomes—nonconsideration, rejection and adoption—are likely to be different and that the failure to distinguish between the three types has affected both

theoretical development and empirical results.

The research reported in this paper addresses this problem by attempting to distinguish between the three different outcomes states and to show the differential relationship of important community structural characteristics to each type. Briefly anticipating the arguments and results, the research shows that on a number of important community structural characteristics there exist significant similarities between communities never having considered a particular policy (fluoridation) and those having adopted it, and that these two types can be distinguished from communities having rejected the policy. On other bases, both rejecters and adopters are similar and can be distinguished from nonconsiderers.

BACKGROUND

Indications of differences between communities classified as never having considered a policy, having rejected or adopted it, are suggested in the literature dealing with the adoption of new programs and innovations by formal organizations. It has been argued by Wilson (1966) and others (Utterback, 1971; Rowe and Boise, 1974; also see Moch and Morse, 1977) that various organizational characteristics may differentially affect the various phases of the innovation process, with this process conceptualized in at least three stages: generating new ideas, proposing new ideas and adopting these ideas. Organizations in which there is an increased capacity to generate many new ideas and programs and to propose them for official consideration, also may be less likely to adopt many of these same proposals. This occurs, according to Wilson, because the organizational characteristics affecting a higher level of idea generation and proposal (complexity of the task and incentive systems) may adversely affect the ability of organization executives to exercise the degree of influence necessary for adopting and implementing these proposals. Complex task structures, involving highly specialized, differentiated and nonroutine tasks, and frequently involving a decentralized task and administrative

structure, contribute to the differentiation of value and reward systems within the organization. In so doing, they reduce the relative value of incentives available for distribution by executives. Hence, a diminution of control over members' activities and task performance and a greater difficulty in instituting new procedures and innovations at the organizational level may result. Conversely, executives in organizations with less complex task and incentive systems may be in a better position to understand, adopt and implement new programs, but the probability that a diversity of new ideas will be generated and proposed is diminished somewhat due to the effects of a relative homogeneity of tasks, organizational expertise and experience, and incentive systems.

Wilson's argument for stages in the innovation process and different organizational characteristics affecting levels of activity at each stage parallels our argument for considering a greater range of community postures and different community characteristics affecting these postures. Communities classified as nonconsiderers may suffer from the failure of new issues and demands being generated and proposed within the community. While at the organizational level this may be attributed to less complex task systems and a less diverse set of values, with fewer alternative reward systems, the analogous structural characteristics at the community level, and variously argued within the literature as affecting outputs, are structural differentiation and community social integration.

Similarly, communities classified as having considered but not adopting a policy may suffer not from a paucity of new ideas being generated and proposed, but from a lower ability to agree on, adopt and implement these proposals. These latter inabilities may be related to the political structure of communities, and in particular, the extent to which decision-making authority is centralized within that structure, as well as to the social integration of the community. Last, communities adopting new proposals may fare well on all accounts. They may have both the capacities for generating new ideas and the abilities to adopt these ideas when

they are perceived as appropriate responses to community problems. In what follows these potential differences between communities are explored and developed into a set of specific hypotheses for testing.

Community Structure and Outputs

1. *Structural differentiation.* The importance of structural differentiation in affecting policy outputs has been noted by Clark (1968a; 1968b; 1973b), Aiken and Alford (1970a; 1970b), Zisk (1972), Hawkins et al. (1975) and others. The essence of this argument is that as communities grow and develop a more extensive division of labor in a number of sectors, comprising a greater number of more complex tasks and specialized organizations and personnel, there emerges new interests, problems and perceptions of issues that are raised for resolution through the political system and a greater degree of expertise for handling novel problems and generating solutions. Thus, in one sense, there exists an expanded and more heterogeneous demand structure in more highly differentiated communities. Moreover, in these communities, the specialized groups and organizations that develop in different issue/problem areas become professionalized, maintain extensive communication networks with extra community organizations and professionals, and are better able to perceive and analyze community problems and suggest potential solutions to them. Hence, the higher level of outputs observed in these communities may be due, *ceteris paribus*, to both the diversity and quality of ideas and proposals that are generated.

This suggests that communities never having considered a particular issue or policy may be distinguished from both adopters and nonadopters by the extent to which the community has developed a number of differentiated, specialized organizations and institutions in a diversity of community sectors.

2. *Community social integration.* The second condition of community social integration and its relationship to outputs has been considered by Coleman (1957), Pinard (1963), and others (Danielson,

1976). Social integration is treated in terms of individual attachment to the community, involving a consensus of values and norms and an extensive and interlocking communications network between community members, organizations and leaders. Coleman's argument relates levels of integration to the potential for controlling the development of community conflict and the debilitating consequences of these conflicts for community decision making and issue resolution (also see Minar, 1966). Thus, where integration is high, the ability of the community to respond to problems and resolve issues is enhanced.

Presumably, the opposite is also likely; i.e., that when perceived needs do not exist and the community is in agreement that a particular condition does not constitute a problem or one that is the responsibility of government to handle, then the more highly integrated community can facilitate nonaction. This is essentially Pinard's hypothesis: that more highly integrated communities are more likely to support their leader's policies, are more likely to take stronger stands for or against a policy, and are more likely to approve or disapprove of policies with greater unanimity than less well-integrated communities.

Following this reasoning, we can argue that higher levels of integration, in addition to directly affecting the likelihood of the adoption of particular policies, are also likely to affect directly their nonconsideration. More highly integrated communities are more likely to agree on a particular position, and where a latent or manifest consensus in favor of a particular policy exists, that policy is more likely to be brought up on the public agenda and approved. Conversely, this same consensus, either on the irrelevance of a particular issue or the inappropriateness of a given policy, will serve to keep it from emerging for public consideration and debate. As such, integration may work in both ways—to enhance the probabilities of adoption or the likelihood of an issue not being considered. Thus, communities classified as nonconsiderers or adopters may be similar and may be distinguished from less well-integrated communities

where consideration and rejection of a policy may be more likely.

3. *Centralization of authority.* The relationship between political structure and outputs has been discussed extensively within the literature. Much of this discussion has focused on the potential "good government" bias of reformed systems and a hypothesized higher level of outputs of progressive, innovative policies in these systems. However, little support exists for this argument. Alternatively, it has been argued that the different political systems—reformed and unreformed—may differ in outputs because of the differences in the ways in which the two types distribute authority. Indeed, the very rationale for the reformed system is given as a means of decentralizing the authority and influence inherent in the partisan, mayor-council system. Thus, reformed structures, while potentially centralizing some administrative authority in the city manager, also may limit the influence of a strong executive, and the formal governmental structure in general, through the mechanisms of nonpartisan elections, and citizen input through the use of referenda, recall, initiative and a greater use of citizen "watchdog" committees (Banfield and Wilson, 1963).

Evidence bearing on the relationship between the differences in centralized authority structures and community outputs comes from Rosenthal and Crain (1968), Crain et al. (1969), Crain (1968), Kirby et al. (1973) (also see Greenstone and Peterson, 1968; Banfield and Wilson, 1963; Moch and Morse, 1977). Rosenthal and Crain's argument is directly to our point, with differences in fluoridation outcomes explained by the degree of executive centralization and participativeness of the system. Partisan, mayor-council systems, it is argued, represent both strong executive centralization and low levels of participation through the use of referenda, and are associated with the highest rate of fluoridation adoptions.

It is not clear, however, that centralized authority is a necessary condition for the adoption of all types of policies and, secondly, that centralized authority need be exercised only for the purposes of adoption. Wilson's argument specifically re-

lates to innovations affecting the entire organization; innovations that bear only on subunits may fare better in a decentralized system (also see Moch and Morse, 1977). This argument is supported by the types of programs (fluoridation and school desegregation) found to be related to centralized authority structures. These programs relate to the entire community rather than to particular community groups and represent those types of programs characterized by Froman (1967) as areal (as opposed to segmental, which are directed to particular groups) and Clark (1973a) as public goods (vs. separable). The hypothesis also parallels the argument given by Smith (1976) and Clark (1973a) concerning the variable relationship between outputs and community power when considering program type (also see Kaluzny, 1974; Zisk, 1972; Lincoln, 1976; Turk, 1970).

Secondly, it is reasonable to argue that centralized authority also may work to keep particular issues from surfacing within a community. Where fewer actors are in control of the official agenda, issues deemed to be untimely, inappropriate or irrelevant by whatever criteria may be more effectively kept from public discussion than in less centralized systems. This suppression of issues is much more difficult in a system of decentralized authority and greater opportunities for public participation since numerous access points to government will exist and their use will be encouraged (Rosenthal and Crain, 1968). In terms of the problem at hand, this reasoning suggests that at least for areal (or public goods) programs, both nonconsiderers and adopters may be distinguished from nonadopters by the degree to which the structure of government involves a centralization of authority.¹

In summary, the main points of our

¹ The relationship between the suppression of issues and community power is discussed by Bachrach and Baratz (1963) and Crenson (1971). Since we do not have the data necessary to test this relationship, the argument is not included in the text. However, given the theoretical literature on this subject a parallel hypothesis concerning the relative concentration of community power in nonconsiderers and adopters appears to be a reasonable one and warrants testing at a later date.

argument can be restated in terms of the following three hypotheses:

1. The greater the level of structural differentiation of communities, the greater the likelihood that they will have considered a particular policy and have taken some action on it, either to reject or adopt. Conversely, the lower the level of structural differentiation, the greater the probability that communities will have never considered a policy.

2. The greater the level of social integration of communities, the greater the likelihood that they will have never considered a particular policy or will have considered and adopted it. Conversely, the lower the level of integration, the greater the probability of having considered the policy and rejected it.

3. The greater the centralization of authority in a community political structure, the greater the likelihood that they will have never considered a particular (areal) policy or will have considered and adopted it. Conversely, the lower the centralization of authority, the greater the probability that the policy will have been considered and rejected.

The following analysis represents a test of these three hypotheses.

METHODOLOGY

Because of its clearly areal nature, the relative ease with which consideration vs. nonconsideration could be determined and the local importance of the issue, water fluoridation was chosen as the particular program by which to test the hypotheses. Much of the data on the three independent concepts of differentiation, integration and the structure of local governments were available from a previous study on 50 communities in New York State. These communities represent the total set of cities of over 10,000 population in 1960 that are located outside of the New York metropolitan area. Data on public activities regarding fluoridation were collected from a number of sources: public documents identifying communities that had adopted fluoridation (New York State Department of Health, 1971), data collected by Simmel (1961) from local newspaper reports on whether the fluoridation

issue was ever publicly discussed within a community, and new data collected by questionnaires sent to the mayor and editor of the local newspaper of each community included in the study. This questionnaire asked each informant whether the community had responsibility for its water supply, whether it had ever publicly considered the fluoridation issue, when, and if so, whether any official action was taken on it. From these four data sources relatively complete and unambiguous data were pieced together for 47 of the 50 communities up through 1965. The analysis is thus based on these 47 communities, distinguished on the basis of never having publicly considered the policy (type I), having considered and rejected it (type II), and having adopted it (type III) up through 1965. The number of communities of each type is 7, 15, and 25 respectively.²

A number of independent variables were selected to measure the three aspects of community structure, as follows:³

1. Structural differentiation, defined as the degree of complexity of community organization and indicated by the extent to which a community had developed differentiated and specialized sets of local institutions, organizations and functions, was measured as follows:

(a) *Guttman scale of commercial services.* The type and range of business and commercial services within a community may be measured on a presence/absence basis in order to indicate both the extensiveness of development of specialties in this sector as well as an indicator of the general differentiation and complexity of the community. Accordingly, a scale of commercial services was created from data on the existence of 25 selected types of business and commercial services originally suggested by Lee (1969) and reported in the Dun and Bradstreet Reference Book (1960). These services range from a fairly "low-order" (such as gas

² Two communities that had adopted and subsequently terminated the program prior to 1965 are included in type III.

³ Data sources for the independent variables, unless noted otherwise, include the 1960 Census of Population and the Municipal Yearbook (International City Managers' Association, 1960-1962).

stations and drug stores) to "higher-order" services (new syndicates, TV broadcasting, specialized business loans) that are likely to be available only in larger, more differentiated communities. Only 12 of the original 25 items were needed to construct the scale, yielding a coefficient of reproducibility of .93 (Guttman, 1947) and a coefficient of scalability of .65 (Menzel, 1953). The resulting scale appears to be intuitively reasonable, with higher scale steps representing the more specialized services found in larger communities (the zero-order correlation between scale score and community population size = .50).

(b) *Closure*. The Guttman scale accounts only for the presence or absence of each specialty within a community, with no account taken of the sufficiency of the level of services that are provided for the population. The concept of closure is intended to account more fully for the level of service by measuring the degree to which these service levels are adequate for the local population. The concept and the particular form of measurement have been developed by Feldt (1965) and are based on the use of location quotients for a selected group of ten local service industries such as food, education, medical services, etc. The index varies about 1.0, with an index below this level reflecting a deficiency in these services within the city's borders. The use of this measurement is based upon the reasoning that more highly differentiated communities are more likely to provide a range of basic goods and services necessary for local consumption. Less developed communities, on the other hand, are likely to be more dependent upon outside sources for the provision of local needs.

(c) *Municipal employees*. Turk (1971) has used the size and functions of municipal bureaucracies as a measure of the integrative and control potentials of the municipal organization over the community units. Following Liebert's (1974) argument, we reason that larger municipal bureaucracies are likely to incorporate a wider range of specialized roles and functions, and therefore are a measure of community differentiation. Municipal employees are measured per 1,000 population.

(d) *City planning employees*. An even more direct measure of differentiation of the municipal bureaucracy and the specialized expertise within it may be the size of particular municipal agencies such as those charged with specialized community development activities. These agencies are likely to be less routine and more professional than a number of other book-keeping or administrative units, and thus more adequately reflect the concept of differentiated, specialized activities and expertise. The number of employees in separate and specialized municipal planning agencies (per 10,000 population) was chosen to reflect the extent to which community development expertise has been incorporated within the community system.⁴

(e) *Occupational structure*. Since particular types of occupations are more likely to be involved in more specialized, complex and nonroutine functions than others, the relative distribution of community occupational roles may be used to reflect community differentiation. This variable is measured as the percentage of the population classified as managers, proprietors or officials and professional, technical and kindred workers.

Three additional variables are included which more directly measure the social heterogeneity of the population than structural differentiation of the community system. These are a gini index of income dissimilarity, the percentage foreign born and the percentage nonwhite. While they do not necessarily capture the degree of specialized knowledge and expertness that form part of our rationale regarding the effects of structural differentiation on proposal generation, these variables do relate to that part of our argument concerned with the diversity of demands that result from a more heterogeneous system.

2. Community social integration, taken to mean the extent to which members are attached to a social system through subscription to a common set of norms and

⁴ Following Liebert's (1974) critique, the use of this variable is dependent on all communities in the study having some formal responsibility in a functional area requiring this expertise. In the present study this requirement is satisfied.

values and participation in a common set of institutions, is measured as follows:

(a) *Index of voting consensus.* This measure is meant to tap the extent to which members of the community agree on particular issues, as a reflection of a consensus on values represented by these issues. It is constructed on the basis of the voting outcomes of thirteen issues presented to the voters between 1958 and 1960. These included proposed changes in state law, state constitutional amendments, gubernatorial elections and political party registration. For each issue, the higher of the two outcome percentages (yes, no; Democrat, Republican) was selected as a measure of consensus on that particular issue and the mean percentage across the thirteen issues was computed as the measure of general community consensus. While imperfect, in that the measure does not account for voter turnout and the relative importance of the particular issues to the community and its members, the measure does appear to be a reasonable alternative to original study and data collection on values and consensus within each community and has much greater depth than measures based solely on one issue, such as presidential voting (cf. Aiken and Alford, 1970a). Voting data were collected from local election boards.

(b) *Moral integration.* Angell's (1951) index of moral integration represents one of the few attempts to directly measure integration in terms of "the degree to which the life of the group proceeds in terms of shared ends and values" (1974: 609). It is computed as a weighted index of crime (from the Uniform Crime Reports) and United Fund contributions (from state and local U.F. organizations) as given in the original (Angell, 1951) formulation, thus representing a further test of the utility of this index beyond Angell's (1974) replication.

(c) *Migration.* The rationale for including a migration variable follows from Pinard's (1963) argument that communities undergoing large population change through migration are likely to be less well-integrated, migration having the effect of disrupting existing social networks (also see Aiken and Alford, 1970a). Given the availability of census data, only

in-migration is measured, taken as the percentage of the 1960 residents living in a different county in 1955.

(d) *Unemployment.* Pinard also argues that high rates of unemployment are likely to impact negatively on community integration since the unemployed tend to isolate themselves and unemployment produces a widespread atmosphere of political apathy and detachment. Unemployment rates are measured for the civilian labor force, 1960.

(e) *Voluntary organizations.* Following Coleman's argument on the integrative effects of community voluntary organizations, a Guttman scale of voluntary organizations was created which reflects the extent of organizational density within the community. The scale consists of nine steps selected from an original list of 25 organizations, with a coefficient of reproducibility = .95 (Guttman, 1947) and a coefficient of scalability = .70 (Menzel, 1953). Examples of organizations included in the scale, in ascending order, are the American Legion, League of Women Voters, American Civil Liberties Union and Congress of Racial Equality (also see Harp and Gagen, 1971). Data were collected from the Chamber of Commerce in each community.

3. Government structure, and the extent to which authority is concentrated within this structure, is measured by five variables, as follows:⁵

(a) *Type of elections.* This is measured as partisan or nonpartisan. Partisan elections, while potentially allowing for more access to local government through the party organization, are taken as reflecting

⁵ Type of government, whether mayor council or manager council, was not included as a variable since there does not appear to be any clear basis for arguing which type involves a greater centralization of authority. While substantial authority for administrative matters may be vested in the manager, policy-making authority on important issues is generally lacking. Similarly, as Rosenthal and Crain's (1968) data indicate, manager cities are more likely to hold referenda and this tendency may be interpreted as an indicator of less centralized authority. Regarding mayoral cities, the distinction between partisan and nonpartisan elections appears to be important, with nonpartisan mayors being relatively weak. Thus, mayor form by itself may not involve more or less centralized authority than manager forms; the critical distinction may turn on type of elections.

a relative concentration of authority. This follows the arguments of Rosenthal and Crain (1968; Crain et al., 1969) concerning the insulating qualities of the party on the mayor and the tendency they find for non-partisan systems to decentralize authority and increase citizen participation through the use of referenda. Support for this interpretation also comes from Greenstone and Peterson (1968).

(b) *Term of mayor.* Also following the reasoning of Rosenthal and Crain (1968), mayors with four-year terms are likely to exercise more authority than those with two-year terms.

(c) *At-large councilmen.* While all reformed structures generally have been regarded as decentralizing authority, it can be argued that each of the reformed characteristics may not have the same effects on distributing authority. Specifically, a greater percentage of councilmen elected at-large may represent a greater concentration of authority in government. Where councilmen are elected at-large there exists lower direct representation and access to government of particular interest groups and areas of the community (traditionally lower income groups and minority areas), and the formulation of a relatively small, elite group who are more independent of any particular set of interests for their election than are ward councilmen. Taking at-large councilmen to reflect a concentration of authority, this variable is measured as the percentage of all councilmen elected at-large.

(d) *Other elected officials.* Other city officials, such as the auditor, clerk, attorney or superintendant of public works, may be directly elected or appointed to office. We reason that authority is likely to be more centralized where these other officials are appointed.

(e) *Composite score.* Since cities vary in the extent to which they incorporate the above four mechanisms of centralization, it is reasonable to argue that those incorporating a greater number of them are likely to be characterized by a greater centralization of authority than those with fewer such mechanisms. Thus, cities with partisan elections, long terms for mayors, a high percentage of at-large councilmen and appointed other municipal officials lie

at one end of a continuum of centralization, with the weak end defined by cities with the opposite set of characteristics. Accordingly, a composite score was created by the simple addition of the number of centralizing mechanisms present in a city, empirically ranging from 1-4.

Each of the independent variables is measured for 1960. In contrast, 68% of those communities adopting fluoridation did so between the years of 1955-65, making it reasonable to measure the independent variables at the midpoint of the decade in which most fluoridation actions were taken.

ANALYSIS AND RESULTS

The analysis was conducted in two parts. In the first, a series of mean comparisons and t-test (frequencies and chi-square in the case of nominal variables) were made for each independent variable taken separately and then with the introduction of controls for each other variable included in the analysis. Because this procedure does not allow for the comparison of all variables taken together, and the study of the relative importance of each, a series of discriminant analyses were undertaken in part two. The latter analysis generally confirms the first and provides the additional information on how well each variable, in conjunction with all others, differentiates between the three outcome types.

The results of the first part of the analysis are shown in Tables 1-3. While it would have been ideal to undertake a three-way comparison of the means or frequencies, the relatively small number of communities used in the analysis and their further subdivision by the control variables argued for certain aggregations. Accordingly, since the hypotheses recognize certain affinities among the different outcome types—integration and centralization of authority should be greater in types I and III compared with II; differentiation should be greater in types II and III compared with I—communities in outcome types I and III were combined when considering the integration and authority variables, and those of types II and III

Table 1. Means of Differentiation Variables by Type of Community

Variable	Type I (7)	Type II, III (40)	p*
Commercial services	8.0	10.1	.03
Closure	.69	.79	.02
Municipal employees	13.4	12.1	.29
City planning employees	.01	.15	.003
Occupation	7.0	7.9	.05
Income dissimilarity	3.9	7.8	.03
Foreign born	7.2	8.2	.09
Nonwhite	2.7	3.3	.35

* One-tailed probability.

were combined when considering the differentiation variables. Control variables are divided at the median unless otherwise noted.⁶

The results of this first part of the analysis provide reasonably strong support for the hypotheses. Reviewing the differentiation variables, Table 1 shows that without controls mean levels of the commercial services, closure, city planning employees, occupational structure and income dissimilarity variables are higher for the type II and III communities and that these differences are significant at $p \leq .05$. Type II and III communities also have more heterogeneity in terms of percentage nonwhite and foreign born and only in the case of the municipal employees variable is the direction of the relationship as hypothesized not maintained. When controls for all other differentiation, integration and government structure variables are instituted⁷ many of these relationships are attenuated, but a relatively large percentage continue to exist in the hypothesized direction (100% of the relationships involving commercial services, closure, city planning employees, occupational structure and income dissimilarity are maintained in the hypothesized direc-

⁶ Since the literature shows that the use of referenda bears a relationship to the probability of adopting fluoridation, it would have been valuable to have added an additional control for method of decision making. Unfortunately, too few of the communities included in the study had used referenda. Of the three employing this method, two had adopted and one had rejected the program.

⁷ Because of the large volume of statistics produced when instituting all controls and the resulting size of the tables needed to reproduce these results, they are not reported here. Copies of these tables are available from the author upon request.

Table 2. Means of Integration Variables by Type of Community

Variable	Type I, III (32)	Type II (15)	p*
Voting	61.5	56.5	.04
Moral integration	6.4	6.9	.13
Migration	10.3	12.8	.06
Unemployment	8.8	9.7	.42
Voluntary organization	4.9	4.7	.33

* One-tailed probability.

tion of which 58% are significant at $p \leq .05$ and 80% at $p \leq .10$).

Results are less strong for the integration variables (Table 2). Without controls mean levels of the voting, unemployment and voluntary organization variables are higher for types I and III than II, and migration is higher for type II, as hypothesized. The differences are significant at $p \leq .05$ only for the voting variable; mean differences are just above this level of significance for the migration variable.⁸ Considering only these two variables, when controls are applied the mean differences are maintained in the hypothesized direction in 91% of the relationships. Of these, 20% are significant at $p \leq .05$ and 47% significant at $p \leq .10$.

Of the government structure variables (Table 3), both the percentage of councilmen elected at-large and the composite score of centralization are shown to be as hypothesized and significant at $p \leq .05$. With controls, all of the mean differences for the councilmen variable are in the hypothesized direction, 50% of which are significant at $p \leq .05$ and 69% at $p \leq .10$. The strength of the composite score distinguishing among outcome types is particularly revealing: apparently, most of the individual mechanisms considered separately are insufficient in themselves to influence outcomes. However, an interaction effect appears to occur so that when taken in conjunction with one another, significant results are obtained. Thus, the results tend to confirm the findings of Rosenthal and Crain (1968) regard-

⁸ The failure of the moral integration index to distinguish between types may be more of a reflection of the validity of this index than of the hypothesis. Potential reasons for the failure of this index are given by Angell (1974).

Table 3. Mean of Percent Councilmen Elected At-Large and Frequencies of Other Government Structure Variables by Type of Community

Variable	Type I, III Type II		Q	p*
	(32)	(15)

* One-tailed probability.

ing the relationship between government structure and fluoridation at a more general, rather than detailed, level.

The second test of these relationships, involving the introduction of all variables into the analysis (the composite score of government structure was substituted for all other government structure variables) was undertaken through the use of a step-wise discriminant analysis and is reported in Table 4.⁹ Variables not making a significant ($p = .05$) contribution to the discriminant equation were successively eliminated so as to produce a discriminant equation whose chi-square probability was $p \leq .05$. Discriminant coefficients are reported in standardized form and may be interpreted as analogous to standardized regression coefficients, with the sign of the coefficient, in conjunction with the sign of the group centroid (representing the position of the type in two-dimensional space) indicating the direction of the effect. Hence, large positive (negative) coefficients increase the probability of a case being a member of a group with a positive (negative) centroid.

Considering the three outcome types separately, three discriminant analyses

⁹ In no instance were the variables correlated with each other at greater than $r = \pm .42$, with most considerably below this, thereby avoiding severe problems of multicollinearity in the discriminant analyses.

Table 4. Discriminant Analyses

Comparisons	Variables										p
	comm. services	closure	c.p. emp.	income diss.	occ.	voting	mig.	score	Group centroids	Canonical correlation	Wilder lambda
1. I vs. II		-1.02		-.64		+.55	-1.03	+.14	I=1.32 II=-.62	.69	.53
2. II vs. III	-.42			-.29		+.72	-.04	+1.03	II=-.76 III=.45	.52	.73
3. I vs. III	-.05	-.93	-.30	-.81		+.19	-.39	+.04	I=1.61 III=-.45	.66	.56
4. I vs. II, III	-.30	-.93		-.60	-.14	+.47	-.68	+.07	I=1.6 II, III=-.28	.56	.68
5. II vs. I, III	-.24	-.18		-.36		+.69	-.27	+.82	II=-.85 I, III=.39	.51	.74

were produced involving each possible pair of types. Our hypotheses suggest that the comparison between types I and II should be the strongest of the comparisons with distinctions occurring on the basis of each of the three structural concepts. Equation 1 of Table 4 shows that the primary bases for distinction between types I and II are, in descending order of importance, migration, closure, income dissimilarity, voting, and the score of centralized authority. Given the negative centroid of type II, we can see that, as hypothesized, the probability of a particular community being a member of this type is increased by higher levels of closure and income dissimilarity (i.e., higher differentiation), higher levels of migration and lower voting consensus (i.e., lower integration) and a lower level of centralization of authority. Conversely, the probabilities of membership in type I are increased by lower levels on the differentiation variables, higher levels of voting consensus and lower migration, and a greater centralization of authority.

Our hypotheses suggest that the differences between types II and III should occur mainly on the basis of the integration and authority variables. Equation 2 shows that the centralized authority and voting variables are the most important in distinguishing between the two types, with further distinctions occurring on the basis of commercial services, income dissimilarity and migration. The probability of membership in type III vs. II is increased by a greater centralization of authority, higher voting consensus and lower migration (integration), and lower levels of commercial services and income dissimilarity (differentiation). While our hypotheses do not suggest that differentiation should be lower in type III than in type II cities, there is no reason to suggest that they should not be slightly dissimilar in this regard. In any event, the effect of the differentiation variables is not substantial; λ is reduced to .77 by the authority and voting variables alone and further reduced by only .04 with the inclusion of the differentiation variables. Clearly, however, given the size of λ and the canonical correlation, the

types may be distinguished further on the basis of variables not included in this analysis.

Of the third comparison involving types I and III, our hypotheses suggest that the primary basis for distinction should be on the differentiation variables. Equation 3 shows that closure and income dissimilarity are the most important, followed by migration, city planning employees, voting, commercial services and centralization of authority. The probability of a community's membership in type I vs. III is increased by lower levels of differentiation, and higher levels of integration and centralization of authority. The inclusion of the migration and authority variables in this equation indicates that types I and III cities, while markedly different from type II, still are not equal in these regards. Of the three types of cities, those never having considered the fluoridation issue are likely to be characterized by the lowest levels of differentiation, the highest levels of integration and the most centralized authority. The correspondence of these three characteristics in type I cities is consistent with our notions of urban development and sociostructural change (Warren, 1963).

If a number of the outcome types are combined, as in the first part of the analysis, then two further (and partially redundant) comparisons can be made. Equation 4, when viewed in conjunction with equation 2 may be seen as a two-stage analysis in which we first consider the differences between considerers and nonconsiderers (equation 4) and then, of the considering group, view the differences between rejecters and adopters. Thus, as equation 4 shows, communities having considered the fluoridation issue are likely to be higher in differentiation (commercial services, closure, income dissimilarity and occupation), lower in integration (lower voting consensus and greater migration) and involve less centralization of authority. Between considering communities however, rejecters are likely to be higher in differentiation and lower in integration and centralization of authority. Equation 5 shows the analysis when types I and III are combined vs. II.

Here the primary distinctions on the basis of the integration and authority variables are maintained.

CONCLUSIONS

The above analysis provides fairly strong support for the three hypotheses. While the analysis was performed on a small sample of communities and therefore may be regarded as only preliminary and promising, the strength of the results and, importantly, the logic of the argument for expanding the consideration of outcome types, suggests a substantial degree of conclusiveness and strength to the implications.

We do not conclude, however, that the three particular structural concepts or the variables measuring them fully explain community policy outputs. While important, a good deal of discriminating ability remains for other variables in each of the discriminant analyses. This argues for better measures of the concepts (particularly community social integration), the inclusion of more variables reflecting these concepts, and the incorporation of still other community structural characteristics in the analysis.

Furthermore, it should be reiterated that the hypotheses and the analysis relate to only one type of program, conceived of here in areal/public goods terms (i.e., those affecting the entire community). Whether or not these results will hold when other areal/public goods programs are used remains to be seen. Similarly, the areal-segmental and public-separable goods distinctions do not exhaust the bases upon which issues and policies can be typed (see, e.g., Salisbury, 1968; Froman, 1968; Lowi, 1964). The clear existence of other dimensions for categorizing policies and their employment in conjunction with one another, may argue for some changes and refinements to the three hypotheses.

We believe that the first hypothesis, relating levels of structural differentiation to outcome types via the reasoning involving diverse demands and expanded expertise is a reasonable one that also may hold when considering other types of pro-

grams. This merely is an extension of research results reported in the literature and the relationship should become even stronger in other studies once the two disparate types of communities usually included in the nonadopt category are distinguished. Our interpretation of current research also suggests that higher levels of social integration may not be a prerequisite for the adoption of programs affecting only particular community groups (i.e., segmental programs) as long as a community maintains that minimum degree of coordination and conflict resolution abilities necessary for maintaining the decision-making system. When segmental programs are involved, it is not necessary that all parties agree on the necessity or desirability of the program and the political trade-offs and compromises that characterize community politics are likely to aid the adoption of segmental, more so than areal, programs. As such, for these other types of programs the distinctions between nonconsiderers, rejecters and adopters may not materialize.

Another question involves the use of centralized authority in actively suppressing or otherwise having the effect of keeping issues from reaching the point of public consideration. We are not certain whether the suppression of areal programs or the suppression of segmental programs may require greater centralization of authority and we can develop hypotheses along each line of reasoning. This, too, remains for further testing.

One conceptual difficulty that also remains is the definition of the nonconsidering category. Throughout we have defined this group as composed of communities in which the fluoridation issue was never raised for public discussion. Our reasoning and hypotheses, however, suggest that this may occur for two reasons: because the issue was never raised at all (either through nonconcern or consensus); or because the issue was either actively or passively suppressed. This suggests that our third outcome category is also a heterogeneous one and that a further refinement of the research should attempt to distinguish between these two subtypes. Given our hypotheses, it is logical to as-

sume that differences between communities of each subtype would exist. Clearly, however, the difficulties in attempting to account for these two subtypes of nonconsiderers are large; how do we readily get at information on cases of active or passive suppression that would be suitable for cross-community research?

Even without making this distinction, questions can be raised about the problems of determining consideration vs. nonconsideration. As noted, the choice of fluoridation in this research partially rested on the relative ease with which nonconsideration could be identified. Given the volatile nature of the issue, it is unlikely that consideration would have gone unnoticed. However, problems still exist. While we relied on newspaper editors and mayors as informants, and have no more than the normal reasons to doubt the validity of their responses and the strengths of their memories, it seems likely that had we surveyed other informants (such as local dentists who may have had more than a passing interest in fluoridation, have discussed it among themselves and have different perceptions of the issue), we may have received different responses.

This also raises the question of when does a particular issue become a community issue; i.e., at what point do we determine that an issue has been considered by a community? The dentists may perceive fluoridation as a community issue while others do not. In other instances the difficulty of deciding if and when a community considered a particular issue may arise because the program "grew" on the community and was adopted incrementally and incorporated into the public delivery system. Many programs are first started by citizen's groups and other non-public organizations at a relatively small scale. Over time these organizations may seek financial help from the municipal treasury for maintaining or expanding the program until, at some point, local government takes over the program, either officially or *de facto*. Thus, the point in time at which the program was considered by the community may be an indeterminate one.

The clearest implication of the research

is the need to more fully account for *at least* three outcome types in future studies. Clearly, however, the implication is not a universal one since for many types of programs the attempt to account for nonconsiderers may be irrelevant or of no practical importance. Where policies are imposed by outside agents, as with court-ordered busing, the notion of when a community considered a policy is irrelevant. Similarly, questions of need and functional responsibility for program areas must be taken into account. Many communities may not consider a program simply because the need for it does not occur (e.g., pollution control in a nonindustrial, rural area) or because the municipality does not have decision-making and service delivery responsibilities. Also, we find it difficult to conceive of many major communities that have not at least considered many of the federally subsidized community programs that have existed for many years and have become standard fare, such as urban renewal and public housing. In these instances, accounting for nonconsiderers may be of no practical significance. Still, beyond these instances a sufficient number of others exist to warrant the consideration of the nonaction community when studying community outputs.

COMMENTS

THE GHOST DANCE AND THE POLICY OF LAND ALLOTMENT*

(COMMENT ON CARROLL, ASR JUNE, 1975)

Carroll (1975) uses the case of the Ghost Dance to test quantitatively hypotheses derived from various theories on the rise and acceptance of revitalization movements. His analysis suggests two prerequisites, either of which is sufficient, for acceptance of the Ghost Dance: recent deprivation and the absence of unilineal kin groups. Acknowledging the methodological advantages of Carroll's choice of the Ghost Dance for study, I suggest an alternative theoretical framework for interpreting the acceptance and rejection of social movements. The assumption underlying my criticisms is not that a deprivation argument is incorrect, but rather that in being applicable to nearly all situations of directed culture contact, deprivation does not particularly reveal how and when mobilization into a social movement takes place. Nor does it allow for much depth in the analysis of the effects of government policy on the rise and spread of movements.

RESPONSE TO CARROLL

The arguments presented by Carroll can be countered in terms of the classification of tribes into high and low acceptors of movements, and in terms of the theoretical frameworks within which acceptance and rejection of social movements can be examined.

In testing his hypotheses, Carroll uses a sample of 37 societies, dichotomized on the basis of high and low acceptance of the Ghost Dance. However, a number of the tribes listed by Carroll in the low acceptance category were in 1889 already involved in other revitalization movements, a factor Carroll should have taken into account. The Commanche and the Mesquero had both adopted the Peyote cult by this time (Slotkin, 1975:36; see also Mooney, 1965:159). Similarly, the Nez Perce partici-

pated in the Smoholla cult (Mooney, 1965:49; Josephy, 1965:434), a natavistic movement similar to the Ghost Dance religion. At this time the Hopi as well were organized in both passive and active resistance (James, 1974:108-22; Josephy, 1968:165). In addition, the basis for Carroll's placement of the Jicarilla Apache in either category is quite tenuous (Brown, 1976). It is improbable that the Jicarilla even knew of the Ghost Dance. Their agent reported they had no such knowledge. Moreover, any information the Jicarilla may have received on the Ghost Dance would have come from the Southern Ute, who were not followers of the doctrine (Mooney, 1965:49).

The Table presented in the Appendix of this paper takes into account the correction mentioned above. Furthermore, Carroll's categorization has been revised on the basis of high and low acceptance of any revitalization movement during the years of the Ghost Dance. Seven tribes remain in the low acceptance category: Fox, Kickapoo, Navaho, Omaha, Santee Sioux, Southern Ute, and Winnebago. This reorganization renders the correlations between revitalization movements and social structure and/or cultural deprivation found by Carroll less useful, as his tests consider only the Ghost Dance and not revitalization movements in general. The recategorization reduces the relationship for deprivation from $\phi = .335$ to $\phi = .241$.¹

While Carroll's arguments have been challenged on grounds of the classification of tribes, other data can be presented and analyzed to test the theoretical frameworks Carroll employs. The implications of this test for a competing theory of social movements can then be examined.

THEORETICAL FRAMEWORKS

In interpreting the high acceptance of the Ghost Dance by some tribes that had knowledge of it and the low acceptance by others, Carroll utilizes two prevailing theories of social movements. Drawing on the work of Aberle (1970), Barber (1941), and Wallace (1956), he constructs a hypothesis to test the role of rela-

I wish to thank John D. McCarthy for his valuable advice throughout the course of this work. His time, enthusiasm, and encouragement were all much appreciated. I also wish to thank the staff of the Rights Protection Office of the Bureau of Indian Affairs for providing dates of allotment of various Indian lands, and the reviewers and editors of the *American Sociological Review* for their useful comments.

¹ Phi is used here rather than Q which is used by Carroll since it is more appropriate. This can be seen since the relationship between deprivation and acceptance of the Ghost Dance is 1.00 using Q, and the relationship presented in Table 2 by Carroll is obviously not perfect.

tive deprivation. In addition, he formulates a hypothesis to test the correlation between acceptance of revitalization movements and a society's level of integration in its Durkheimian sense, i.e., the degree to which an individual feels a sense of solidarity with some social group (Carroll, 1975:397). Here Carroll subscribes to the mass society theory of social movements. Two propositions follow from the mass society theory. The first is that extremist social movements are most likely to flourish in societies in which few people participate in associations. Secondly, it is the alienated and atomized individuals who make up the ranks of such movements (Oberschall, 1973:103).

In explaining the unequal levels of acceptance of the movement, Carroll thus supports a theory based on degrees of integration; he suggests that acceptance of a revitalization movement is a response to a lack of cohesion within the groups that compose the society. This integration argument can be tested by examining the effects of the allotment of land in severalty, a legislative policy designed to destroy the tribal cohesion of American Indian societies.

THE LAND ALLOTMENT POLICY

The policy of allotment of Indian lands in severalty took form in the 1870s (Otis, 1973:3). Pressure for passage of a General Allotment Act came from white settlers and lumber, railroad and mining interests who hoped to gain access to surplus Indian lands on the one hand, and "philanthropists" who hoped to instill the notion of private property and thereby civilize the Indians, on the other. What little acceptance of the policy there was on the part of Indian groups came as an attempt to protect their land holdings. It was hoped that an individually-held strip of land, guaranteed by a patent from the government, would provide greater security than tribal possession. Such was the concern of the Omaha who petitioned for allotment of lands in severalty in 1882 (Otis, 1973:13-4).

The General Allotment, or Dawes Act, as passed in 1887 provided for each family head to be allotted 160 acres of land, with lesser amounts allotted to other individuals. The allotments were to be held in trust by the United States Government for twenty-five years in order to protect the lands from land-greedy speculators. The choice of allotment was to be made within four years after allotment was applied to the reservation, with failure to choose a parcel of land resulting in selection on the order of the Secretary of the Interior. Citizenship was to be conferred upon

allottees and on all other Indians who had abandoned their tribes. Lands "left over" after individual allotments had been assigned were to be opened up to white settlement.

The goal of the legislation's promoters was to do away with tribalism, with communal ownership of land, with the concentration of the Indians on reservations, with the segregation of the Indians from association with good white citizens, with Indian cultural patterns, with native languages, with Indian religious rites and practices. . . . (Prucha, 1973:7).

Senator Dawes, an ardent proponent of allotment whose name became attached to the legislation of 1887, explained that the idea of allotment

is to take Indians out one by one from under the tribe, place him in a position to become an independent American citizen, and then before the tribe is aware of it its existence as a tribe is gone. (quoted in Priest, 1969:246-7)

Figures on the transfer of land ownership from Indians to whites bear witness to the effect of the Dawes Act (Otis, 1973). Of the 155,632,312 acres of Indian lands in 1881, there were 104,314,349 acres left in 1890, and 77,865,373 acres in 1900 (Otis, 1973:87). The lands held by Indians thus were cut nearly in half as a result of the allotment act.

Allotments on the Santee Sioux reservation preceded the Dawes Act by two years, and at that location 42,160 were opened to white settlement (Meyer, 1967:182). By 1909 two-thirds of their land retained in separate allotments had passed out of Indian ownership (McNickle, 1973:84).

In 1890 the agent of the Omahas and Winnebago estimated that 60% of Winnebago land belonged to women, old or infirm men, and minor children, none of whom could cultivate it (Prucha, 1976:258). While the Omaha and Winnebago had been the great hope of allotment enthusiasts, most of the evidence from the 1890s and later "piece together a picture of a demoralized people" (Otis, 1973:131). The passage in 1891 of a law allowing for leasing of Indian allotments removed even more land from Indian hands, and further opened the reservations to white settlers.

In general the literature on the effects of allotment of land in severalty reveals

how allotments opened up reservations, led to the extinguishment of title to "surplus" tracts and created, through homesteading, a mixed Indian country. . . . The thrust and conclusions of most studies suggest . . . that allotment was failing and that contrasts between tribal and allotted land use patterns revealed how the latter was destroying tribal life and creating indigent and landless Indians. (Sutton, 1975:126-7)

Implementation of the allotment policy on a reservation was significant in the disintegration of the tribe's previously existing community structures. The relationship of societies in which allotment of land took place before knowledge of the Ghost Dance had been received, with level of acceptance of the movement, therefore will offer some evidence of the role of integration in acceptance of social movements.

If two tribes which had strong religious barriers to the Ghost Dance are eliminated,² five tribes remain in the low acceptance category. These are the Fox, Kickapoo, Omaha, Santee Sioux, and Winnebago. The latter four tribes were each allotted before Wovoka's revelation in 1889: the Kickapoo in 1865 (Gibson, 1963:135), the Omaha in 1832 (Fletcher, 1972:624), the Santee Sioux in 1870 and again in 1885 (Meyer, 1967:182), and the Winnebago in 1871 and 1876 (information provided by the BIA). According to records of the Bureau of Indian Affairs (U.S. Department of the Interior, 1977), the Fox were allotted lands in 1891. Thus their reservation was allotted before Mooney visited them, but as he does not state when the Fox first heard of the Ghost Dance it cannot be determined if it was before or after allotment took place. Nevertheless, for purposes of statistical analysis the Fox are included, and the year 1889 used as a cut-off date. This is the year of the Paiute Messiah Wovoka's revelation and the initiation of the Ghost Dance religion.

According to available information, with the exception of allotments to 55 Pawnee families in 1882 (Hyde, 1951:342), all tribes that fall within the high acceptance category either were never allotted or were allotted lands in severalty after 1889. There therefore appears a

high correlation between the allotment of lands in severalty and low acceptance of the Ghost Dance.

If we employ the categorization of tribes in the Appendix, the relationship between allotment and low acceptance appears as $\phi = .61$; if the Navaho and Southern Ute are discounted (see fn. 2), the relationship appears $\phi = .76$. As can be observed, this relationship is stronger than either of those which flow from Carroll's arguments.

MOBILIZATION THEORY

The correlation is of theoretical significance in the study of social movements. It supports the contention that movements are most likely to occur in contexts of preexisting social networks and are least likely to take place in contexts of social disintegration. The evidence thus suggests a competing argument to the mass society theory presented by Carroll, and lends support to a mobilization theory of social movements as described by McCarthy and Zald (1977), Freeman (1975) and others.

An assumption underlying the mobilization argument is that social strain creates only the potential for social movements and not the movements themselves. Assuming the existence of collectivities or quasi-groups with grievances, Oberschall presents a classification of collectivities on the basis of the degree of both vertical and horizontal integration. In a society which is segmented, i.e., in which there are few bonds between the collectivity and others higher up in the stratification system, the greater the horizontal integration the greater the tendency to accept a social movement. In other words, "rapid mobilization does not occur through recruitment of large numbers of isolated and solitary individuals. It occurs as the result of recruiting blocs of people who are already highly organized and participants" (Oberschall, 1973:125).

In a more specific application of this perspective, Freeman (1975) presents a model proposing three prerequisites for mobilization into a social movement: one or more precipitants, cooptability, and a preexisting communications network. Previously organized networks are conducive to the rapid rise and acceptance of social movements. The least disintegrated groups are those most likely to mobilize. Taking this approach, one would expect a lack of integration to tend to hinder the acceptance of a revitalization movement.

If land allotment can be taken as an indication of a breakdown in tribal integration (as the literature strongly suggests it can), we do indeed find low acceptance of the movement in

² There is evidence to indicate that both the Navaho and the Southern Ute were faced with strong ideological barriers to acceptance of the Ghost Dance doctrine. In aboriginal Southern Ute ideology, a ghost can claim a relative in death. Opler (1963:189) notes that when a personal emissary to the Southern Utes stated that Ute ancestors would come from the west in bodily form, and set the time within the next year, "The Ute waited, torn between fear of the actual ghostly visitations (which, according to their own beliefs spelled death for the living) and doubt that such an event could ever happen." A similar fear of ghosts can be found among the Navaho, and Hill (1965:511) suggests that this accounts for their low acceptance of the Ghost Dance.

For the Navaho with his almost psychotic fear of death, the dead and all connected with them, no greater cataclysm than the return of the departed or ghosts could be envisaged. In short, the Navaho were frightened out of their wits for fear the tenets of the movement were true.

those tribes which had, in Oberschall's terms, low horizontal integration, or in Freeman's terms, in those tribes which did not have a preexisting communications network.

POLICY AND SOCIAL MOVEMENTS

The high correlation between land allotment and low acceptance of a revitalization movement is of additional significance. It points to the value of examining the relationship between policy and social movements, and in particular, to the importance of land policies in American Indian movements.

Keeping a population physically separated so that no sense of common interest or solidarity can easily develop may be regarded as a way of preventing potential partisans from organizing (Gamson, 1968). In this sense the policy of abolishing communal land ownership and of allotting lands in severalty served as a mechanism for social control, and discouraged acceptance of a social movement.

In addition to breaking up the preexisting communications network then, the policy of allotment of land in severalty had social control effects by reducing incentives for joint action; furthermore, by removing control of land from the tribal organization, the policy greatly limited the field of authority of native social and political structures.

It has often been observed that one cannot talk about American Indians without talking about the land; in the United States the Indians are the only "territorial" minority (Sutton, 1975:ix). Land continues to be the focal point of conflict between Indians and the larger society. The findings in this analysis of the Ghost Dance lend weight to Sutton's (1975:2) observation that "the reservation not only has sustained tribal culture, but also has formed the base from which to generate a new native nationalism." This study suggests the potential in examining the role played by land policies in movements for tribal self-determination.

REJOINDER TO LANDSMAN*

One of my goals was to encourage researchers to use the case of the Ghost Dance to test quantitatively hypotheses relating to revitalization movements. I am pleased to see that Landsman has done just that. Unfortunately, there are several methodological errors in her

comment that make it difficult to evaluate her substantive argument.

What I originally hypothesized is that if a society has social structures which provide the individual with a strong sense of attachment, then such societies would be less likely to accept a revitalization movement like the Ghost Dance. Assuming that unilineal descent groups promoted this sense of attachment, I predicted that the presence of such groups should have been negatively correlated with acceptance of

* Address all communications to: Michael P. Carroll; Department of Sociology; University of Western Ontario; London, Ontario N6A 5C2.

the Ghost Dance. The original data supported this prediction.

Landsman argues that four tribes (the Comanche, Mescalero Apache, Nez Perce and Hopi) should be reclassified from *low* to *high* acceptance on the basis of their involvement with movements other than the Ghost Dance, and strongly implies that this reclassification would weaken my results. This implication is incorrect. Three of these tribes (the Comanche, Nez Perce and Mescalero Apache) lack unilineal descent groups (cf. Murdock, 1967) and therefore my hypothesis quite clearly predicts that they *should* have been high acceptance tribes. In fact, reclassifying these four tribes as Landsman suggests raises the correlation (I'll use phi, since she prefers it) between low acceptance and the presence of unilineal descent groups from .36 (in the original analysis) to .42. If we drop the Jicarilla Apache from the sample, as Landsman further suggests, the correlation increases to .48, since the Jicarilla Apache lacked unilineal descent groups and yet were coded *low acceptance* in the original analysis.

Admittedly, these reclassifications would weaken the support for the other hypothesis that I considered, which linked acceptance to relative deprivation. But I considered this hypothesis only because it is quite well-established in the literature on revitalization movements. The hypothesis which linked acceptance to the absence of unilineal descent groups, on the other hand, was new and was perhaps the most original theoretical contribution of my article. Personally, then, I am more than willing to accept any reclassifications (such as Landsman's) that would undercut the traditional deprivation hypothesis in favor of the hypothesis (involving unilineal descent) that I developed myself.

But though I am so inclined to accept the suggested reclassifications, I must nevertheless point out that these reclassifications involve several errors. Note that Landsman has redefined the dependent variable from "acceptance of the Ghost Dance" to "acceptance of any revitalization movement." Her first error then is that she has limited herself to my initial sample, which included only those societies that had been exposed to the Ghost Dance. She makes no attempt to include in her analysis tribes not in my sample but which might nonetheless have been tribes very much involved in one of the other movements that she mentions. An example will illustrate the problem.

Landsman reclassifies the Nez Perce on the grounds that they were involved with the Smohalla cult. But Mooney (1973:708-46)

makes it clear that the adherents of this cult were widely scattered among the tribes of the Columbia River Basin. In fact, in his section on this cult, Mooney discusses over three dozen tribes from this region, virtually all of which were *not* included in my sample (as they were not involved with the 1889 Ghost Dance). If Landsman were truly interested in the study of "revitalization movements in general" and wished to seriously include the Smohalla cult in her analysis, then she would have to go through Mooney's discussion and classify these additional tribes into high and low acceptance categories.

There is, however, the distinct possibility that Landsman may be unaware of that section of Mooney's report in which he gives an extended discussion of this cult. She cites only the 1965 Phoenix edition of his work. This is an abridged version that deletes over 100 pages of Mooney's original text, notably including those sections in which Mooney discussed Indian movements, such as the Smohalla cult, that existed prior to the Ghost Dance. (The original report was published in its entirety as a Dover reprint in 1973.) If Mooney's discussion of these other cults was missed because the abridged version of his work was used, then this is simply sloppy scholarship.

Actually, the Smohalla cult is a particularly unfortunate case for Landsman to have mentioned. Mooney (1973:720-1) reports that Smohalla himself knew about the land allotment laws discussed by Landsman and regarded land allotment as contrary to Indian cosmology. This alone, without invoking arguments about isolation and communication, could account for a negative correlation between the establishment of land allotment and the acceptance of Smohalla's doctrine.

But perhaps Landsman's most serious error occurs in her reclassification of the Comanche and the Mescalero Apache on the grounds that they were involved with the Peyote cult. My own knowledge of the Peyote cult is minimal, but even a quick consultation of a single source (LaBarre, 1975) turns up six cultures in Landsman's sample (the Shoshone, Winnebago, Kickapoo, Omaha, Fox and Navaho) in which a Peyote cult began to flourish only *after* the year that she gives as the year in which land allotment was established for the culture in question. Since she argues that land allotment should prevent the acceptance of social movements, all six cases are inconsistent with her argument.

In short, by reclassifying *only* the Comanche and the Mescalero Apache, Landsman has reclassified only those cases that help her argument. If the reclassification of cultures on

the basis of their involvement with either the Ghost Dance or the Peyote cult is done systematically (which at least means reclassifying not simply the Commanche and the Mescalero Apache, but also the six tribes just mentioned), then the correlation between low acceptance and land allotment drops from the impressive .61 that Landsman reports to the less impressive .16.

Given the confusion that results from Landsman's attempt to deal with "revitalization movements in general," the best way to evaluate her theoretical argument is again to restrict ourselves to the Ghost Dance. If this is done, which means placing the Commanche, Mescalero Apache, Nez Perce and Hopi back into the low acceptance category, then the correlation between low acceptance and land allotment is .43. If we drop the Jicarilla Apache from my original sample (for the same reasons that led Landsman to drop the Jicarilla from her sample) then the correlation between the presence of unilineal descent groups and low acceptance is .40. The two correlation coefficients, given the small sample size, are virtually identical, and it is fair to say that both hypotheses are equally well supported by the data.

But while Landsman accounts for the correlation between low acceptance and land allotment by arguing that land allotment destroyed a community's ability to organize a social movement, an alternative argument—and one perfectly consistent with my own theoretical reasoning—is possible. Note first that land allotment was not widespread prior to 1889: Landsman lists only five tribes in which land had been allotted prior to that date. Which tribes, do you suppose, would have been singled out as the early targets of the land allotment policies?

If Landsman's summary of the motivations driving those whites who promoted land allotment is correct, then one of their goals was to undermine the hold that various tribal collectivities had over the Indians. With such a goal, the most obvious targets would have been those tribes in which such collectivities did in fact exert a strong hold over their members. Furthermore, my original argument was precisely that unilineal descent groups were collectivities of just this sort.

Putting all this together leads to the very straightforward prediction that those cultures with unilineal descent groups would most likely have been the early targets of land allotment laws and policies. If we take the 35 tribes in Landsman's sample and cross-tabulate "presence/absence of unilineal kin groups" (from Murdock, 1967) with "land allotted prior

to 1889/land unallotted in 1889" (from Landsman's table), then the correlation is strong (.46) and in the expected direction (unilineal tribes *were* more likely to have been subjected to land allotment prior to 1889). In other words, the data suggest that the presence of unilineal kin groups both reduced the likelihood that a culture would accept a revitalization movement *and* made it more likely that that culture would become the target of land allotment laws. This would indeed produce a (spurious) correlation between low acceptance and land allotment.

In summary then, there is nothing in Landsman's comment that leads me to question either the hypothesis that I originally developed in connection with unilineal descent groups or the evidence that I advanced in support of that hypothesis. Landsman *has* turned up a correlation between low acceptance and land allotment, but this is a relationship that is easily taken into account by my original theory.

THE EFFECTS OF POLITICAL PARTICIPATION AND SOCIALIST PARTY STRENGTH ON THE DEGREE OF INCOME INEQUALITY

(COMMENT ON HEWITT, ASR JUNE, 1977)*

Prior to the publication of Hewitt's (1977) research, the findings of the cross-national investigation of the determinants of inequality were contradictory and inconclusive due to such crucial problems as inadequate operationalizations of income inequality and

* Address all communications to: Steven Stack; Department of Sociology; Alma College; Alma, MI 48801.

different measures of political democracy (Jackman, 1975; Peters, 1973; Cutright, 1967; Parkin, 1971). Hewitt's (1977) well-designed paper makes a substantial contribution to the resolution of these problems. His results are based on more valid and reliable data than most of his predecessors and should be given more weight by scholars in the field. For example, he uses a theoretically sound measure of income inequality based on household income as opposed to relying on an approximate measure based on sectoral income. His findings provide strong evidence against the position of Jackman (1975) and others that political democracy does not influence inequality independent of the level of economic development. In addition, Hewitt provides the first systematic test of the relationship between socialist party strength and the degree of inequality. The results of this part of his analysis support Lenski's (1966) theory that governments dominated by socialist or labor parties will bring about the greatest reduction in stratification. Finally, the impact of socialist strength on inequality is found to be greater than the impact of simple democratic structures on inequality.

The present paper's concern is to provide a brief critique of the part of Hewitt's paper that deals with the income inequality dimension of stratification. There are two methodological shortcomings in this part of his work. First, his index of simple democracy emphasizes dimensions of political organization that may not be the key sources of political pressure for redistribution. These include the number of years a nation has had the secret ballot and responsible government or the election of officers to the executive branch. Hewitt's measure of simple democracy emphasizes the mere skeleton of democratic political organization. Alternative measures of political democracy that get beyond the elementary structure could very well lead to different results. For example, if we measure political democracy in terms of the degree of political participation, for example, the degree to which the citizens exercise their rights to suffrage and the secret ballot, we might find that it is more of an important factor than suggested by Hewitt's research. Second, Hewitt fails to investigate the relationship between political variables and the overall degree of income inequality. While the determinants of the income share of top income groups are an important concern, it is also appropriate to investigate the determinants of the general degree of income inequality.

The present study reanalyzes Hewitt's data using an index of political democracy which measures the degree of actual participation in

politics. We contend that democratic political organization may not have a substantial impact on reducing inequality unless a relatively large proportion of lower status citizens take advantage of democratic structures. Our measure of political participation is the proportion of the adult population that voted in 1965.¹ As Erbe (1964) argues, political participation varies directly with social class status. As voter turnout increases proportionately more persons from the lower social classes are exercising their right to vote and there is more pressure for the election of persons that will represent their interests and for policy that will benefit their group. For example, we know that the higher the voter turnout, the higher the proportion of blue-collar workers, labor leaders, and other nontraditional groups that are elected to parliaments and cabinets (Wences, 1967; 1969). We would anticipate that parliaments composed of high proportions of such nontraditional groups would be more likely to favor policies to reduce inequality. Since it is known that groups with relatively low socioeconomic status have more "liberal" attitudes on economic policies, and are more aware of serious welfare problems, more concerned with the gap between the rich and poor, and are more supportive of government programs for the poor, we would anticipate that the greater their participation in politics, the greater the probability that government will reduce inequality through such means as minimum wage laws, full employment policies, welfare expenditures, and progressive taxation (Huber and Form, 1973; Verba and Nie, 1972).

We anticipate that the political participation of lower status groups and socialist party strength are significantly related. The presence of a socialist party should foster such participation since it favors the interests of the less privileged groups in society.² However, in societies without strong socialist parties, and there are many in the group of nations under investigation, we would anticipate that relatively high political participation would lead to the rise of egalitarian movements within estab-

¹ The data on voter turnout were taken from Taylor and Hudson (1972) and from Russett et al. (1964) for three missing cases. Data on all other variables were obtained from the same sources as in Hewitt (1977). We decided to restrict the number of independent variables to three variables since as Blalock (1972:468) points out, as the number of variables approaches the number of cases the results of regression analysis may be unreliable due to the differentially high reliance on chance fluctuations.

² In the present study the Pearson Product Moment correlation between socialist party strength and voter turnout is .59.

SOC: Mean socialist party strength in parliament, 1945-1965.

* Statistically significant at the .05 level ($p < .05$).

lished nonsocialist parties. For example, the American Democratic party is not classified as *socialist* by Hewitt, but it has been a key force in implementing policies to reduce inequality. Our transfer payment system, for example, significantly reduces the amount of income inequality and some careful research indicates that it is just as effective in the reduction of inequality as the much heralded system of "socialist" Sweden (Reynolds and Smolensky, 1977; Rosenthal, 1967: 135-53). We anticipate that high political participation will influence inequality in the absence of an official socialist party and that it will have an effect on income inequality that is independent of socialist party strength.

The present investigation will add a third dependent variable to the analysis of income inequality, the Gini index of income inequality, which measures the overall degree of income differences. The Gini coefficients were obtained from the same source Hewitt used to derive his data on the income shares of the top 5% and top 20% of the population (Paukert, 1973).

We use energy consumption per capita as our control variable, the same indicator that was used by Hewitt for the level of economic development. Finally, in order to measure the relative merits of political participation as a determinant of income de strati fication, we use Hewitt's measure of the degree of social democracy, the mean proportion of seats held

by socialist parties in parliament from 1945-1965.

Table 1 gives the results of the regression analysis concerning the determinants of the degree of overall income inequality. The most important determinant of general inequality is our index of political participation (beta = -.541). When the level of development and socialist party strength is controlled for, the greater the voter turnout, the less the inequality. Socialist strength bears no significant influence ($p < .10$) on income inequality once we control for voter turnout and level of development.

We find similar results if we measure income inequality in terms of the share of the top 5%. The data in Table 2 illustrate that if we control for the other independent variables, voter turnout is the factor that is most closely associated with low inequality (beta = -.454, $t = -1.937$, $df = 14$, $p < .05$). Again, once we control for the other variables, socialist party strength lacks a significant relationship with inequality of incomes.

However, as the regression results in Table 3 indicate, if we measure income inequality in terms of the income share of the top 20% of households, voter turnout is not significantly related to inequality ($p < .05$) once we control for socialist strength and level of economic development. Socialist party strength is significantly related to the income share of the top fifth. With the other two variables in the re-

gression controlled for, the greater the socialist strength, the less the income inequality. However, the level of economic development (beta = -.440) is more significantly related to inequality than is socialist strength (beta = -.413).

Our results indicate that an operationalization of political democracy which stresses political participation, as opposed to the structural elements of democracy, is a better predictor of the level of income inequality than social democracy as measured by socialist party strength. It is useful to make a distinction among three definitions of democracy in terms of its basic structure, level of participation, and the relative power of socialist parties. Previous research has emphasized the first and third definitions. The present paper provides support for the study of a third relevant definition of democracy in research dealing with inequality.

REPLY TO STACK*

Stack's main point is a good one. He argues that by emphasizing the structural characteristics of political democracy¹ my

* Address all communications to: Christopher Hewitt; Department of Sociology; University of Maryland Baltimore County; 5401 Wilkens Ave.; Baltimore, MD 21228.

¹ I would like to correct a misprint in the original article. The date given in Table 2 for the attainment of responsible government in Italy should be 1919 not 1959.

analysis ignores the extent to which citizens take advantage of such democratic structures. His measure (voter turnout) is a plausible operationalization of this latter aspect of democracy. However, there are some problems with his position.

The crucial assumption is that increased voter turnout with a concomitant increase in the proportion of lower-class voters will result in "political pressure for redistribution." This would seem to be true *only* if the electorate is mobilized along class lines. In a number of countries, however, the salient political cleavages are religious or ethnic. In Italy, the Netherlands and Germany, confessional parties account for 40–50% of the vote (Russett, 1964). It is striking that the two countries with the highest voter turnout are Italy and the Netherlands, suggesting that high electoral participation by lower socioeconomic groups may result from religiosity as well as radicalism. Ethnic voting in Trinidad resulted in an 88% vote in the 1961 election. Malik (1971:121–2) comments that this high turnout was due to "a greater awareness of the major political issue involved: vindication of the racial pride of the respective ethnic groups."

The only evidence cited for the assumption that high voter turnout leads to the election of persons representing and policies benefiting lower-class interests is Wences (1969). Yet Wences appears to argue that representation of the lower-middle and lower classes in the political elite is only token regardless of voting rates (1969:186, 188) and that the recruitment of labor leaders to cabinets "is heavily dependent on the electoral success of left-wing parties closely identified with labor organizations" (1969:185). Surely this is evidence for the importance of socialist parties rather than voter turnout?

One important difference between Stack's democratic variable and my social-democratic one may account for the difference in our findings. I argue that the effect of politics in democratic societies is incremental and must be measured over a period of time. Stack measures voter turnout in 1965 only. Yet in Venezuela and Argentina military juntas ruled for most of the 1945–65 period. Surely a measure of electoral participation should take the *absence* of elections into account? Even where elections are regular events voter turnout is highly variable and presumably therefore a single election will be unreliable as a measure of egalitarian pressure. Fourteen countries in Stack's analysis which are listed in Mackie and Rose (1974) had a mean variation in electoral turnout since 1945 of 12.3%. In Trinidad electoral turnout varied from a high of 88.1% in

1961 to a low of 32.9% in 1971. Thus the variation in turnout within one country was far greater than the variation between *all* the countries in Stack's sample—excluding South Africa.²

Despite these problems, Stack's finding that voter turnout is correlated with equality is interesting. To decide between socialist party strength and voter turnout as factors in reducing inequality is difficult given the small data set and the high intercorrelations between the political variables. Subsequent research by focusing on government policies and relating policies to both political factors and economic equality may resolve the issue.

DIALECTICAL ANALYSIS AND CLOSED SYSTEMS: CLASS SOCIETIES OR WORLD-ECONOMY?

(COMMENT ON APPELBAUM, ASR
FEBRUARY, 1978)*

In highlighting aspects of the Marxian method that are typically distorted in conventional sociological renderings, Appelbaum's (1978) contribution is most welcome. The reduction of dialectics to a heuristic device, the generalization of historically specific struggles into transhistorical universals about "conflict," the severance of necessary links be-

² Excluding South Africa (where voting is restricted to whites and the rate in consequence is only 14.3%), the country scores range from 89.2% (Italy) to 56.8% (United States).

* Address all communications to: Walter L. Goldfrank; Dept. of Sociology; Merrill College; University of California; Santa Cruz, CA 95046.

tween social scientists as theorists and social scientists as living practitioners in a concrete present—all these features of standard sociological thought deserve critique and rebuttal. One can further applaud Appelbaum's insistence that social theories ought to explain change at the social level (although it is hard to believe that anyone ever took seriously the notion that population growth is a biological, rather than a social phenomenon). In referring to social change, Appelbaum thus uses such phrases as "endogeneous structural social change" (p. 68), "endogenous structural change" (pp. 74, 79), "endogenous social change" (p. 70), "change as internal to actual sociohistoric systems" (p. 74).

Endogenous at the social level, yes. But endogenous means *within*, and hence the question arises, *within what?* Appelbaum assumes that the proper unit of analysis for capitalism is class society. That is, like the standard sociologists he criticizes, he is mystified by and perpetuates the fetishism of the nation-state. Such a fetishism is contradicted by his own explication of the conditions which modify the tendency for the rate of profit to fall through the interaction of C (constant capital), V (variable capital), and S (surplus value). *Some* of those conditions occur largely within the boundaries of the nation-state (here nineteenth century England, since the example is drawn from *Capital*, Vol. 1): for example, the theoretical skill of working-class leadership, the tolerance of capital for working-class organization, monopolization of the means of production, technical change.

But other conditions, crucially, do *not* occur within nation-state boundaries. Among those mentioned by Appelbaum himself are "the ability of capital to extract surplus from foreign workers to the advantage of domestic workers," "cheapening the means of subsistence" (in the concrete case, Corn Law repeal), "shifting production to colonies with a ready source of cheap labor," "extend[ing] capitalist economic relations abroad (e.g., foreign investment, which permits the importation of cheap raw materials and machinery produced with low-paid foreign labor)" (p. 78). Another condition affecting C, V, and S via the class struggle—especially interesting given the example of nineteenth century England—is the migration of labor: the import, temporary and permanent, of foreign workers, not only the Irish;¹ and the export of surplus artisans, farm-

ers, and other workers, who in the absence of the opportunity to settle in the United States or the colonies might well have changed the terms of the struggle. That so-called competitive capitalism could have developed in England as it did, to take textile manufacture as the leading sector, is utterly inconceivable without markets wider than England itself and without cheap cotton from the slave South. "In fact, the veiled slavery of the wage-workers in Europe needed, for its pedestal, slavery pure and simple in the new world" (Marx, 1867: 759–60).

One could go on elaborating the world-systemic conditions that made "English" competitive capitalism possible; but the general point ought to be clear. The unit of analysis within which capitalism operates as an actual sociohistoric system is a *world-economy*,² not an array of nation-states, societies, or social formations. Capitalism, after all, is merely the transition from (European) feudalism to (world) socialism. Historical social science taking *systematic* aim at the structures, transformations, and perhaps developmental stages of this moving target is in its youth (for a recent summary, see Research Proposal, 1977), though surely it builds on major traditions of inquiry, most importantly Marxism. In the analysis of change, "endogenous structural change" if you like, "surplus value, production for exchange, and class conflict" (p. 79) are indeed critical concepts, though not the only ones. The phenomena to which they refer move within a dynamic totality, the capitalist world-economy. Many of Appelbaum's conditions modifying the tendency of the profit rate to fall require the introduction of untheorized phenomena outside the boundaries of the English nation-state. This should give him and other Marxists pause as we make the theoretical, empirical, and practical advances we seek.

Walter L. Goldfrank
University of California, Santa Cruz

¹ "... the London labour-market is always overstocked with German and other candidates for death in the bakeries" (Marx, 1867:267).

² *World-economy* is used here in the technical sense of two or more politically sovereign units interdependent with respect to the flow of necessary commodities. Only in the past 75 years has the modern capitalist world-economy begun to reach the asymptotic inclusion of all the populated regions of our planet, removing the theoretical possibility of *geographically* exogeneous change. Perry Anderson (1974:172–360) provides an interesting example of such change in the past with his discussion of the effects of the seventeenth century East European wars on the development of Sweden, Prussia, Poland, Austria, and Russia.

RESPONSE TO GOLDFRANK*

Walter Goldfrank's comment is well-taken and, as he acknowledges, in no way contradicts the main thrust of my argument, which was to suggest ways in which a Marxist analysis is fruitful for comprehending processes of social change. While Marx utilized an abstracted model of capitalist economic relations in *Capital* (from which my argument derives), it is clear that an adequate theoretical formulation must consider national economies within the framework of a world economic system. This was already true in Marx's time, and is far more so today, as Goldfrank notes. While I continue to believe that such concepts as surplus value, production for exchange, class conflict, and the like will prove to be central in providing an understanding of the bases of endogenous structural change in contemporary societies, I strongly concur that the frame of reference must ultimately be the global economic system. This will, in turn, modify the theoretical categories with which we work, as currently "untheorized phenomena" become incorporated within the body of Marxist economic and social theory.

PARSONS'S VOLUNTARISM

(COMMENT ON ALEXANDER, ASR APRIL, 1978)**

I found Alexander's (1978) article interesting both for what it includes and for what it passes

* Address all communications to: Richard P. Appelbaum; Department of Sociology; University of California; Santa Barbara, CA 93106.

** Address all communications to: John W. Heeren; Dept. of Sociology; California State College; San Bernardino, CA 92407.

over. Of the first sort, he nicely points up that a central theme in Parsons's work is resolving the free will of man and the directionality of social change. Unfortunately Parsons is no more successful at this than earlier thinkers. Emphasis on the continuity in Parsons's work leads Alexander to neglect some contradictions and questionable assumptions of Parsons.

(1) Rather than it being the continuing basis of his substantive voluntarism, Parsons's formal voluntarism is ultimately eclipsed by his analysis of systems and differentiation. When Parsons argues that action is organized into systems and that these are normatively oriented, where then is the actor's choice or will? One's membership determines his action.

(2) Where is the actor's voluntarism if the direction of change—increasing differentiation—is inevitable? It is interesting that Parsons (1937:753) had criticized Weber for his "fatalistic interpretation of the process of rationalization." This sense of inevitability is much stronger in Parsons's later work than it was in Weber's. His recently developed evolutionary scheme seems to represent Parsons's discovery of the path of history. Indeed, Parsons (1966:4) sees a need to explain the coming of feudalism in Europe since it is the "most radical structural regression in the history of major societies." Presumably, those who currently favor a "small is beautiful" philosophy also would be considered regressive.

(3) The real significance of differentiation comes out in *Economy and Society*. Here Parsons and Smelser (1956:83) "discover" the correspondence of their concrete and analytic systems when they argue that concrete societies tend in general to differentiate along the lines of the Parsonian four-function scheme (1956:83). Thus, we are told that the family is "specifically located in the pattern-maintenance sub-system of the society" (1956:53).

(4) The hypostatizing of the theory is carried far enough so that Parsons (1964) in one essay suggests that the processes of differentiation should lead to the development of a new occupational role: the spiritual counselor who is intermediate between the minister and the therapist.

(5) In spite of Alexander's statement that Parsons used a conception of multidimensional causality, the more important fact is that Parsons (1966:113) imputes priority to cultural elements in the evolution of societies. Moreover, the implication is strong in his recent work that religious values are perhaps the most important elements within the cultural sphere.

(6) Alexander properly notes that Parsons's

substantive voluntarism is evaluative. More than this, the implicit value placed on individual autonomy is inconsistent with a significant portion of the sociological tradition. However much Marx and Durkheim would seem to be poles apart on other sociological issues, an argument could easily be made that they "converge" in their negative assessment of individualism in modern society. And contrary to Alexander, Marx's image of man hunting in the morning, fishing in the afternoon, and criticizing after dinner could be seen as representing significant dedifferentiation.

ONCE AGAIN: THE CASE FOR PARSONS'S VOLUNTARISM*

Mr. Heeren has reiterated criticisms which have become the stock-in-trade of Parsons interpretation. Far from being unaware of the points he raises, I directed much of my reinterpretive efforts precisely to such objections. After years of partial misinterpretation and often misleading debate, the process of incorporating the important breakthroughs that Parsons achieved will, evidently, be a difficult and uneven one. Old myths die slowly.

Let me make four points:

(1) Voluntarism is not antithetical to systems analysis, nor, certainly, is it antithetical to normative control. One of the primary reasons for distinguishing, as I did in my article,

between the formal and substantive elements in Parsons's work is to point to the multilevel character of any social theory. There is a wide range of diverse components in any theory; these components may be viewed as forming a continuum from the most general kinds of commitments to the most specific (Alexander, 1980, Vol. 1, Pt. 1). Every theory contains general presuppositional commitments (what I called theoretic-epistemic, or formal elements), as well as very specific propositional statements which are much more directly derived from empirical observation. In between these two poles of the continuum, there are a number of other kinds of commitments. Ideological assumptions, for example, derive neither from presuppositions nor from empirical observation; combined with empirical propositions, however, they form the substantive elements of a sociological theory.

Another kind of intermediate element, and here we come to the issue of systems, is the kind of model a theorist chooses. The fundamental point here is that commitments to models and commitments to presuppositions vary independently. A multidimensional, voluntaristic approach on the theoretic-epistemic level can be combined with systemic models, and the result will be a voluntaristic model of social systems. On the other hand, an instrumentalist, deterministic approach at the presuppositional level, which disallows the resort to transcendent values upon which voluntarism must be based, also may be combined with a systemic model. In this case, the system theory in question will, indeed, be antivoluntaristic and deterministic. Far from his system model pushing him into an overly rigid determinism, there is, in fact, the danger that Parsons's model will slip into an overly voluntaristic position. Insofar as his presuppositional synthesis of idealism and materialism falters, this slippage frequently occurs.

To respond to a related point, voluntarism does not depend on whether an "actor's choice" is preserved, nor does it depend on whether or not an actor is described as a "member" of a normative system. In the first place, every concrete actor has a choice in every concrete situation. Parsons has never denied free will in this limited sense; he has spoken, rather, of the probability that norms will be followed in a given instance (Parsons and Shils, 1951:155-6). These norms, of course, might be, in substantive terms, highly individualistic and critical ones, so that the conformity to norms cannot be confused with conformity in the pejorative, common sense use of the term. This observation leads to my second point: it is a nominalist error, associ-

*Address all communications to: Jeffrey C. Alexander; Department of Sociology; University of California; Los Angeles, CA 90024.

ated with classical liberalism and neo-Kantian theory, to identify voluntarism with free will in the strong sense, that is, with the actions of a completely nonconstrained and nonsocialized actor. There is a long tradition in social thought, most recently exhibited by Durkheim, Freud, and Piaget, which believes, correctly in my opinion, that freedom depends, in part, on certain distinctive internal qualities which are produced only through association and internalization.

(2) As this last point helps to clarify, Parsons certainly does not advocate individualism in the *laissez-faire* sense of the term, but rather the socially-constrained exercise of individual choice. This intention, of course, is the reason for his characterization of the modern situation as one of "institutionalized individualism" (Parsons, 1967). As I tried to demonstrate in my article, Parsons's individualism is rooted, first of all, in an epistemological critique of individualistic theories like utilitarianism. His substantive theory, furthermore, tries to synthesize, with the classical liberal commitment to the individual, the approaches to individual freedom imbedded in more collectivist theories in both the materialist and idealist traditions (Alexander, 1978a:183-6). To argue that individual freedom rests upon universalistic values and upon strong bureaucratic and legal controls on the unfettered market does not impress me as an endorsement of individualism, nor as substantially different from the general positions proffered by Durkheim and Marx.

On the other hand, as I also mentioned in my article, Parsons does often exhibit an overly optimistic attitude toward the institution of private property, and often accepts with equanimity the psychological consequences of a cultural emphasis on individualism. Insofar as Parsons veers towards such an individualism, it is fair to say that he has abandoned his synthesizing impulse on the substantive—empirical and ideological—level of his theory.

(3) Parsons does not consider differentiation to be inevitable, as Mr. Heeren's own example from *The Systems of Modern Societies* demonstrates very well. Parsons does indeed describe feudalism as a "drastic regression" in western history, and he spends a good deal of time analyzing the social structure of this period (Parsons, 1971:33-45). Does this imply that differentiation is inevitable or, indeed, that Parsons believes precisely the opposite? Developmental theorists, like Freud and Piaget, outline the mental structures necessary for psychic health and cognitive maturity; does this mean that Freud and Piaget believe that every individual will grow up to be healthy and

perceptive? In the same monograph, Parsons also analyzes the countries of the Counter-Reformation, specifically, how their less differentiated, more ascribed structures prevented them from capitalizing on the opportunities for development presented by the Renaissance, as western European nations were able to do (Parsons, 1971: 40-3, 49-54, 71-4). This does not sound like inevitable differentiation to me.

I would agree, however, that Parsons is often overly optimistic about the emergence of differentiated structures. One of the primary justifications for this optimism is his insistence that differentiation is produced by a system's need for "functional adaptation" to structured, long-term disequilibrium. Less optimistic than Parsons, I wonder whether a bureaucratic state, less differentiated from the legal and religious systems, might not be more adaptive, in many respects, than a democratic, more differentiated system. It was this question which prompted me to make one of the distinctions I emphasize in my article, namely, that an ideological commitment to individual emancipation has affected, and perhaps made less realistic, Parsons's understanding of the actual course which societal differentiation takes.

(4) Finally, I would certainly not argue that Parsons's theory is internally consistent, nor did I do so in my article (Alexander, 1978a:192-4). Like many other great theorists (see, for example, my discussion of Weber in Alexander, 1978b), Parsons's work is deeply ambiguous, about both formal and substantive issues. As I think I made clear, I wrote this article in order to emphasize the positive elements in Parsons's contribution.

1970 CENSUS FIGURES ON PUBLIC ASSISTANCE INCOME: SOME COMPARATIVE FIGURES FROM ALTERNATE SOURCES*

(COMMENT ON LONG, ASR FEBRUARY, 1974)

The conclusions drawn in the Long (1974) article about the propensity of black and white migrants to six large American cities (New York, Philadelphia, Chicago, Detroit, Los Angeles and Washington, D.C.) to be poor (cf. U.S. Bureau of the Census, 1973a:x, for definition) or to be receiving welfare during the year 1969 as compared with persons born in these cities, for the same year, were based on information obtained from the 1970 census.

In this connection, the writer wishes to mention two studies published in 1972 which reviewed data reported in the 1970 census on public assistance income, or welfare. The first is a RAND study entitled "Two Counts of Welfare in New York City: A Comparison of City and Census Data for 1969," by C. Peter Rydell (1972). This study, as its title indicates, compared official statistics published by the New York City (1969) Department of Social Services on the total number of welfare cases receiving assistance and total cash disbursements for the year 1969 with the same figures which were published in the 1970 census.

The study concluded that "the 1970 census of population underestimated the number of welfare cases and the amount of welfare income in New York City during 1969. In both instances the census estimate was essentially 40 percent below the city's estimate" (Rydell, 1972:7). The exact figures were a 41.1% underestimation of total cash grants and a 39% underestimation of total cases.

This study compensated for the different time frames used in the census statistics (yearly totals) and the city figures (monthly totals) and also for the fact that the census counted a single family which included two or more cases as a single case, while the city counted it as two or more cases. The latter

disparity was compensated for by preparing estimates of the duplication of cases in the census figures and adding this figure to the original census total.

The writer is not currently in possession of similar studies of official figures for other large cities as compared with those published in the 1970 census. The second study to be mentioned, however, "Preliminary Evaluation of 1969 Money Income Data Collected in the 1970 Census of Population and Housing," by Mitsuo Ono (1972), does provide information about money income statistics for each state in the Union, although not for individual cities. This study is referred to by the Census Bureau (1973a) in its introduction to the 1970 census subject report on "Low Income Areas in Large Cities." However, it is not referred to in the introduction to "Mobility for Metropolitan Areas" (1973b), wherein the statistics on which the Long paper is based are located. Also the studies' specific conclusions are not noted in the introduction where it is mentioned; however, it is given as a reference in which "estimates of income underreporting in the 1970 census" (U.S. Bureau of the Census, 1973a:xi) may be found.

The Ono study compares the aggregate incomes from various sources as reported in the 1970 census (wage or salary income, self-employment income, social security, public assistance income) with benchmark estimates of the same figures which have been compiled by the Bureau of Economic Analysis. The benchmark figures are independent estimates of the above income aggregates obtained by analysing "administrative data sources" (Ono, 1972:391). The Ono study does not indicate exactly what administrative sources were used; however, the Bureau of Economic Analysis (1976:35) itself in a later publication entitled "Local Area Personal Income, 1969-1974," states that its sources for information on public assistance during this period were based on county information on the amount of benefit payments made. The information was available annually from State Departments of Welfare and/or the National Center for Social Statistics of the U.S. Department of Health, Education and Welfare.

The benchmark figures for public assistance income in the 1970 census as reported in the Ono paper range from 55% for Iowa to 101% for Indiana. The average for the United States is 69%. The averages for the states where the cities mentioned in the Long article are located are: New York, 61%; Pennsylvania, 71%; Illinois, 69%; Michigan, 72%; California, 64%; and Washington, D.C., 73%.

* Address all communications to: Christopher B. Norton; 102 W. 80th St., Apt. 63; New York, NY 10024.

This study thus estimates that the 1970 census statistics for public assistance income varied from between 55% and 101% of their actual totals and averaged only 69% of the total for the country as a whole.

It would appear that the 41% underestimation indicated in the Rydell study would substantiate the 61% projection given in the Ono paper for New York State. Unfortunately, as indicated, the Rydell statistics covered only New York City while those in the Ono paper are for New York State as a whole.

If the 1970 census did underestimate American public assistance income by 69%, as the Ono study indicated, it probably underestimated the number of cases receiving public assistance also, as attested to by Rydell for New York City.

The question which the results of these two studies pose for the Long paper concern its conclusion that a larger number of black natives to the metropolitan areas mentioned above were on welfare during the period surveyed than black migrants to the areas. Would the statistics substantiate this conclusion if the analysis were made of the actual welfare population?

The percentage differences on which Long's (1974:49) conclusions about black welfare recipients were based were rather small and varied from 1 to 4.2%. If the balance of the welfare population not counted (assuming the census did undercount total welfare grants and number of cases) did have the same percentage of natives and migrants as those census respondents who answered questions on place of origin, the conclusions would remain the same. Since there does not appear to be any way of determining this, the writer feels that the Long article's conclusions about welfare recipients are not necessarily supported by census data.

One further question which presents itself concerning the census data is the advisability of asking questions of respondents about public assistance income if the accuracy of the responses is only 69%. Perhaps the procedure used in the last two census counts (1969 and 1970) of mailing questionnaires to families who complete them without supervision and then mail them back to the Bureau on census day (self-enumeration) should be revised so that better statistics are forthcoming.

Hopefully those preparing the 1980 census will utilize sampling procedures which will produce results that are not as open to question as those discussed here.

REPLY TO NORTON*

The main points of the preceding comment seem to be twofold and include: (1) the discovery that income was underreported in the 1970 census, and (2) the belief that income underreporting could be substantially reduced through personal interviews rather than the mail-out/mail-back technique used in the 1970 census. The first point is clear to anyone who has ever worked with census or survey data on income; the second point is questionable; and neither invalidates the conclusions I reached in "Poverty Status and Receipt of Welfare among Migrants and Nonmigrants in Large Cities" (Long, 1974).

In the ASR article I argued that during the 1960s black South-to-North migrants who had lived in northern cities for a few years were slightly less likely to be poor or on welfare than blacks who had grown up in these cities. This

* Address all communications to: Larry H. Long; U.S. Department of Commerce; Bureau of the Census; Washington, D.C. 20233.

conclusion contradicted some of the conventional wisdom which asserted that black migrants were more likely than black urban natives in the North to be on welfare either because they migrated in order to get welfare or they migrated for other reasons and were forced to rely on welfare as a result of inability to secure stable employment.

A later article published in *AJS* (Long and Heltman, 1975) sought to provide a fuller rationale to the ASR findings. The *AJS* article showed that black migrants who had lived for a few years in the North were more successful in escaping poverty and welfare dependence partly through higher rates of labor force participation. The migrants had taken lower status jobs but, in the aggregate, managed to earn slightly more than the urban natives because proportionately more of the migrants were working. The data presented in the two articles came from the 1970 census, which in urban areas was taken through the mail-out/mail-back technique thought by Norton to have biased the income statistics. Under this procedure, first used in the 1970 census, households in the sample were mailed a questionnaire, and if it was mailed back with complete answers by the due date, no interviewer would come by. If the questionnaire was not mailed back or if it was mailed back but was incompletely filled out, then an interviewer would be sent to the address. This procedure was adopted partly because of cost considerations and was thought to reduce interviewer bias.

The general validity of the picture sketched in the ASR and *AJS* articles does not depend simply on data from the 1970 census. Independent data sources have verified the higher income of the black South-to-North migrants during the 1960s or thereabouts. Weiss and Williamson (1972) analyzed the 1967 Survey of Economic Opportunity, a national sample sponsored by the Office of Economic Opportunity, and found higher incomes among the black South-to-North migrants than blacks of similar background characteristics but born in the North. A similar empirical result was reported by Hogan and Featherman (1977), who analyzed the 1973 Occupational Change in a Generation survey, a large nationwide sample. Using still another survey, the National Longitudinal (Parnes) Surveys, Adams and Nestel (1976) found that younger blacks who had moved from the South to the non-South in the 1960s or earlier had higher earnings than blacks of the same age but native to the non-South. Finally, using a special match of Social Security records and test scores of men taking the Armed Forces Qualifying Test, Cutright (1972; 1974) reported higher earnings in 1964 for black

migrants from the South than for black non-migrants in the non-South.

In addition, the 1960 census, which, contrary to Norton's belief, was not taken by the mail-out/mail-back technique, also indicated higher income and higher rates of labor force participation among the black South-to-North migrants than among blacks native to the North (Masters, 1972; 1975; Lieberman and Wilkinson; 1976). Altogether, the aforementioned studies come from five completely independent data sources, with data collection taking place in various years between 1960 and 1973. All found higher income or earnings, taking age and some background factors into account, for the black migrants from the South. All five data sources were from personal interviews, except for the Cutright (1972; 1974) studies, which used data from administrative records and therefore contained no sampling error. None of these data sources relied on mail-out/mail-back techniques.

Despite some differences in definitions of variables, the consistency of findings among independent studies presents overwhelming evidence as to the basic correctness of the empirical facts regarding the relative income position of black migrants from the South vis-à-vis black northern nonmigrants during the 1960s. The higher income and higher labor force participation on the part of the migrants who had lived in the North for a few years certainly implies less need for welfare. It is important to note, however, that recent migrants generally experienced more unemployment, lower income, and greater dependence on welfare than the long-term migrants (Long, 1974; Long and Heltman, 1975). Return migration seems not to account for this difference between recent and long-term migrants (Long and Hansen, 1977), suggesting that the migrants initially experienced some unemployment and low earnings before going on to surpass the earnings of the urban nonmigrants.

If the South-to-North black migrants (at least those who had lived in the North for a few years) had less apparent need for welfare because of higher income vis-à-vis the urban natives and if the migrants' higher income resulted from higher labor force participation, the more basic question boils down to this: Why did the migrants have higher labor force participation? The answer, again coming from several completely independent sources, appears in substantial part to involve differences between the migrant and nonmigrant groups in job expectations and attitudes toward work and welfare. In somewhat oversimplified terms, the answer seems to involve the migrants having lower expectations regarding

satisfactory working conditions, their emphasis on the pecuniary aspects of a job (rather than nonpecuniary aspects like enjoying the work, having pleasant coworkers, etc.), and having less knowledge of the alternatives to work (see Adams and Nestel, 1976; Koziara and Koziara, 1968; Northrup, 1968). The general thrust of these and other studies was to point out some of the disadvantages that can accrue to blacks as a result of reaching adulthood in northern ghetto areas and how work attitudes of black migrants during this time allowed them to overcome some of the traditional handicaps of southern birth.

These studies brought about some fundamental rethinking concerning the sources of inequality between blacks and whites in northern cities and the causes of urban problems in the North. Prior to the publication of the studies cited above, black South-to-North migration was thought to be a dominant explanation of both the large socioeconomic difference between blacks and whites in the North and the source of many urban problems like crime, unemployment, and welfare dependence. Perhaps Banfield (1968; 1972) was the most widely publicized proponent of the theory that black South-to-North migration could largely account for black-white income differences and many urban problems in the North.

The interweaving of results reported by different researchers using different data sources produces a reasonably consistent picture of black migrant/nonmigrant differences in the North in the 1960s. The census, of course, had income underreporting, and the best discussion of this and other sources of error affecting comparison of income differences between migrant and nonmigrant blacks in the North in 1970 can be found in Lieberman (1978). Taken in context, however, the 1970 census results on the socioeconomic position of black migrants and northern nonmigrants agree with other data in their broad description of the situation.

One should avoid generalizing the results for the 1960s to earlier periods or to the future. In earlier periods, it is extremely doubtful that the black South-to-North migrants could overcome their educational handicaps so as to match or exceed the northern nonmigrants in earnings. But by the 1960s the educational level of black South-to-North migrants was nearly equal to that of blacks native to the urban North (Long and Heltman, 1975), and under such circumstances other factors like attitudes toward work and welfare began to loom more important in differentiating migrant and nonmigrant northern blacks.

Since 1970 fewer blacks have been moving

North, and more have been leaving the region to go South. In fact, the North now has net outmigration of blacks—a striking change from the 1960s (U. S. Bureau of the Census, 1978). A significant question to be investigated with data from the 1980 census is how successful the northern-born have been in competing with the southern-born for the expanding number of jobs in the South.

THE "ECOLOGICAL APPROACH" AND COMMUNITY LEADERSHIP

(REPLY TO LINCOLN AND OLSON, ASR
 FEBRUARY, 1978)*

Lincoln and Olson (1978) have organized an array of mainly minor or contrived issues around three more general criticisms of our (Grimes et al., 1976) study of community structure and leadership arrangements. Reacting to each *specific* criticism would involve the reader in much nitpicking and more time and space than most of the issues warrant.

Their first concern is with our use of the term *ecological* and the criteria we used to make our evaluation. They suggest that our approach is not ecological because it "bears little relation to ecological theory" (p. 112, emphasis ours). In fact, we took pains when writing the article to avoid the use of the term theory because no valid theory of adequate scope can be found in the community leadership literature. This has been noted by others (e.g., Walton, 1970; Warren, 1977) and may be inferred from Lincoln and Olson's reliance on two citations to a single theory which has received no little amount of criticism (e.g., Straits, 1965; Williams, 1973). We made no claims to introduce or test a *theory*, but our hypotheses were easily related to that extant body of community leadership literature which can be readily recognized by Lincoln, Olson and anyone else researching the topic when the term *ecological* is used. Accepting their very narrow definition of ecological would exclude significant works

ranging from some of the Chicago school classics (e.g., Zorbaugh, 1929) to recent research such as that subsumed under the currently accepted label of factorial ecology (e.g., Rees, 1971).

Our evaluation of the ecological hypotheses is criticized on the same page (p. 113) for, first, having an "exaggerated concern with the magnitude of R^2 " and, second, for expressing "disappointment in the R^2 's—although these, which range up to .43 are not trifling by prevailing standards." Something is awry here. Either R^2 is a valid indicator of importance or it isn't. We believe that it is and that there is more to the story than Lincoln and Olson mention in their comment: our data showed a *lack of consistency* in the R^2 's across the different measures of the dependent variable and some of the relationships were opposite to those predicted by an examination of the previous literature.

A second concern is with our multidimensional conceptualization of leadership and the manner in which it was used. Here, as elsewhere, Lincoln and Olson extract a minor example (the degree to which democracy and pluralism overlap) rather than a major point (e.g., the relative merits of multidimensional vs. unidimensional conceptualizations), make unwarranted assumptions (e.g., that the latter is dependent upon the former), and overlook those sections of our text which explicitly answer some of the questions they raise (e.g., measures of all four leadership dimensions were not used on a single sample of communities because "[r]egrettably such a data set, to our knowledge, does not yet exist," (Grimes et al., 1976:713). We were also chided for not presenting the zero-order correlation coefficient for the association between the legitimacy and visibility dimensions. The R^2 happens to be .42, which neither adds to nor takes away from our conclusions. In the context of the criticism, should it be regarded as more than "trifling" by prevailing standards (p. 113) or would this be an "exaggerated concern" (p. 113)? Finally, it was suggested that the most rigorous approach would have been to "treat leadership structure as an unobserved construct" (p. 114). Lincoln (1976) tried this himself and thus he should know why we avoided it. It demands specific theory about causal ordering and this is sadly lacking in the relevant literature.

Finally, several criticisms are offered concerning the means by which we derived the community structural variables in our analysis. We employed factor analysis as a data reduction technique—no more, no less. As such, it was successful in organizing the various indi-

 jean; Department of Sociology; University of Texas;
 Austin, TX 78712.

cators of community structure used by others. Moreover, the initial variables—and thus the factors—were representative of the extant demographic data available for communities from standard sources (Bonjean et al., 1969). That the original analysis was performed on counties was a necessary compromise to achieve sufficient scope and simultaneously to include cities of less than 25,000 in the universe. That it probably makes little difference whether counties, cities or some other boundary is used has been noted by investigators who have compared the findings from such analyses (e.g., Bonjean, 1971; Foley, 1977). Such comparisons also reveal that the removal of a few variables (e.g., the budgetary data) fails to influence the emergence of most of the factors identified.

In short, some of Lincoln and Olson's criticisms are of exaggerated points taken out of context. Others can be resolved by examining the references cited in our article. Most disappointing, however, is the failure of their criticisms or the comment in general to offer constructive suggestions for the improvement of research on community structure and leadership arrangements.

ITEMS (Continued)

search activities include studies of decision making in the criminal justice process and studies of victims of personal crimes. With Michael Hindelang and James Garofalo, he has coauthored *Victims of Personal Crime: An Empirical Foundation for a Theory of Personal Victimization*. (Ballinger, 1978). **MICHAEL J. HINDELANG** is Professor in the School of Criminal Justice, State University of New York at Albany. Currently he is involved in studies of self-reported delinquency methodology, the utility and limitations of various criminal justice statistical data, and victims of crimes. In addition to his work with Gottfredson and Garofalo, he has authored *Criminal Victimization in Eight American Cities* (Ballinger, 1976).

■ **DONALD BLACK** (Comment: Common Sense in the Sociology of Law) is Associate Professor in the Department of Sociology at Yale University. He is doing cross-cultural and historical studies of dispute settlement. He is author of two forthcoming books, *Studies on the Police* and *Toward a General Theory of Social Control* (Academic Press).

■ **ROBERT V. ROBINSON** (Class as Conceived by Marx and Dahrendorf) is Lecturer and Ph.D. Candidate in the Department of Sociology at Yale University. His research focuses on rationales for and perceptions of inequality in England and the United States. His dissertation is a ten-nation study of determinants and consequences of control of the means of production and authority. **JONATHAN KELLEY** is Senior Research Fellow in the Institute of Advanced Studies, The Australian National University. He also is Lecturer in the Department of Sociology at UCLA. He is working on a comparative analysis of social mobility. Recently he completed a monograph entitled *Revolution and the Rebirth of Inequality: The Bolivian Revolution* (coauthored with Herbert S. Klein).

■ **J. ALLEN WHITT** (Toward a Class-Dialectical Model of Power) is Visiting Assistant Professor in the Department of City and Regional Planning, Cornell University. He also has an appointment in the Sociology Department at Brown University. He is doing research on the political and social implications of corporate interlocking directorates and elite social networks.

■ **JILL S. QUADAGNO** (Paradigms in Evolutionary Theory) is Assistant Professor of Sociology at the University of Kansas. She is working on an investigation of the social and economic conditions concerning poverty among the rural aged (in collaboration with Scott G. McNall).

■ **PATRICK D. NOLAN** (Size and Administrative Intensity in Nations) is Assistant Professor at the Pennsylvania State University, Schuylkill Haven.

He is interested in macrostructural research on the effects of the political economy of the world system on the relative size of police and governmental subsystems.

■ **WALTER R. GOVE** (Overcrowding in the Home; Possible Causes of the Apparent Sex Differences in Physical Health) is Professor in the Department of Sociology and Anthropology at Vanderbilt University. His Research interests center on mental illness, sex and marital roles, crime, aging, drug use, and the effects of crowding and isolation on human behavior. **MICHAEL HUGHES** is a Ph.D. Candidate in the Department of Sociology and Anthropology at Vanderbilt University. He is studying mental hospitalization. His dissertation is on living alone and mental well-being in the United States. **OMER R. GALLE** (Overcrowding in the Home) is Associate Professor of Sociology and Director of the Population Research Center at the University of Texas, Austin. His research focuses on developing a comprehensive measure of system change, the relations between migration and age structure as it relates to traditional models of migration and further explorations in the area of crowding and behavior.

■ **RICHARD A. SMITH** (Decision Making and Non-Decision Making in Cities) is Associate Professor in the Department of Urban and Regional Planning, Florida State University. His research interests cover the areas of community structure and policy outputs, housing discrimination and segregation and the social impacts of public policy. Currently he is beginning a study of the social impact assessment processes in Great Britain.

■ **GAIL LANDSMAN** (Comment on Carroll, ASR June, 1975) is a graduate student in the Ph. D. program in sociology at the Catholic University of America.

■ **STEVEN STACK** (Comment on Hewitt, ASR June, 1977) is Assistant Professor of Sociology at Alma College. Currently he is working on cross-national studies of suicide. He also is investigating the relationship between unemployment rates and crime rates.

■ **WALTER L. GOLDFRANK** (Comment on Appelbaum, ASR February, 1978) is Associate Professor of Sociology at the University of California, Santa Cruz. He is studying social change in the period between the two world wars.

■ **JOHN W. HEEREN** (Comment on Alexander, ASR April, 1978) is Associate Professor at California State College, San Bernardino. His research centers on schools in contemporary American sociology.

AMERICAN SOCIOLOGICAL REVIEW

THE FOUNDING OF THE *AMERICAN SOCIOLOGICAL REVIEW*: THE ANATOMY OF A REBELLION*

PATRICIA MADOO LENGERMANN

George Washington University

American Sociological Review 1979, Vol. 44 (April):185-198

The establishment of the *ASR* in 1935 conventionally is seen as a rebellion against the influence of the Chicago School on the profession. Drawing on hitherto untapped archival materials, this paper attempts to resolve an ongoing controversy about the sources of this rebellion. It outlines the events in the rebellion, identifies the protagonists in the conflict, and describes the reasons for conflict. The rebellion was led by "association" men, rebelling against a variety of elitist trends in the professional community. The event occurred in the context of a variety of practical stresses resulting from the Depression. My account of this episode is related to a contemporary debate in the sociology of science about the nature of scientific change.

Most commentators agree that the history of American sociology during the first third of this century is inseparable from that of the department of Sociology at the University of Chicago, the so-called Chicago School (Coser, 1977; Gouldner, 1970; Hinkle and Hinkle, 1954; Martindale, 1960). Nothing better symbolizes this interdependence than the fact that Chicago's journal, *The American Journal of Sociology* (*AJS*), functioned as the official journal of the American Sociological Society (ASS) until 1936, giving the Chicago department extraordinary centrality in professional communication. During the thirties, however, the American sociological community was turbulent with conflict and hostility, much of it directed towards Chicago and to the issue of its influence in the profession. This hostility came to a head in 1935 when the ASS

voted to establish an independent journal for the Society, the *American Sociological Review* (*ASR*). The decision to disestablish the *AJS* was construed both by contemporaries and by later commentators as a rebellion against Chicago.¹ In turn this rebellion is treated both as symbol and cause of Chicago's loss of professional centrality, which dates from about this time (Bernard, 1973; Coser, 1977; Faris, 1967; Kuklick, 1973; Martindale, 1976; Odum, 1951).

Apart from this agreement, however, details on the rebellion are few, and interpretations of its causes and outcomes varied and confusing. This confusion is demonstrated in the conflicts among three well-known versions of the incident.

¹ Interviews with Leonard Cottrell and Peter Lejins. Also supporting this view of the episode as an antagonistic act against Chicago is the well-known statement of the rebels' leader L. L. Bernard:

I . . . appointed the committee which recommended the substitution of the *American Sociological Review* for the *American Journal of Sociology* and pushed the resolution through to its adoption. . . . I took these steps because the department of sociology at the University of Chicago under its leader at the time had become arrogant and was suspected of making the interests of the American Sociological Society subsidiary to those of the Chicago department. (Odum, 1951:410)

* Address all communications to: Patricia Madoo Lengermann; Department of Sociology; George Washington University; Washington, D.C., 20052.

Research for this paper was supported by a National Endowment for the Humanities Summer Research Fellowship (1976) and by a Post-Doctoral Fellowship from the American Association of University Women (1976-1977). I wish to thank Dr. Jessie Bernard for first pointing me in the direction of the L.L. Bernard papers, and Dr. Herbert Blumer for his detailed comments on an earlier draft of this paper.

1. Faris (1967) argues that the rebellion was the work of an activist faction, politicized and socially involved, who challenged Chicago's stand on scientific detachment and value neutrality. This prompted a counterrebellion by Chicago and its allies, embodied in the founding of the Sociological Research Association (SRA), "a fortress to which the objective scholar might retreat . . ." (Faris, 1967:121-2).²

2. Martindale (1976) describes the rebellion as the work of a band of "Young Turks" spearheading the quantification movement and radically positivist in orientation, who rebelled under the banner of scientific objectivity against Chicago's broad, humanistic outlook. Martindale credits this group with the founding both of the ASR and the SRA, and treats their hard-nosed scientism as "a response to the economic crisis" of the thirties. (Martindale, 1976:71-4).³

3. Kuklick (1973) relates the rebellion to a broader pattern of theoretical reorientation during which theoretical influence shifted from Chicago sociology to the structural-functionalist perspective centered at Harvard and Columbia. The rebels were younger men, often "products of new sociology departments . . . not schooled in deference to Chicago" (Kuklick, 1973:3). Although they held no systematically articulated theory at the time of the rebellion, the elements of this were already apparent and would soon coalesce into structural-functionalism. Like Faris, Kuklick treats the SRA as a counterrebellion by Chicago, but an ineffectual one.⁴

This paper brings new data to bear on this argument. These data come primarily from the collection of L.L. Bernard's papers in the archives of the Pennsylvania

State University. Bernard is acknowledged by most sources as the leader of the rebellion against the AJS (Bernard, 1973; Barnes, 1968; Kuklick, 1973; Odum, 1951; interviews with Herbert Blumer, Leonard Cottrell, Everett C. Hughes, Helen McGill Hughes). I also draw on interviews and correspondence with people who were professionally active in the thirties, and on published accounts and records of the profession in that decade.

This report is intended primarily as an historical account, a description and analysis of a concrete sequence of events which has had an immediate shaping effect on the contemporary experience of American sociologists. The literature referred to so far illustrates the persistent curiosity in the profession about this episode. The main part of this paper: (i) outlines the chief events in the rebellion; (ii) identifies the combatants; (iii) describes the issues which drove them to conflict; (iv) assesses the consequences of the rebellion.

A second aim of this paper is to relate the data on the founding of the ASR to an issue of contemporary theoretical relevance: the three-way debate among sociologists of science about the nature and sources of scientific change (Lengermann, 1978). Table 1 summarizes the main features of this controversy. Broadly speaking the argument centers on three views of science: the developmentalist view, which sees any science as a system of roles and norms; the Kuhnian view, which sees any science as a community sharing a distinctive paradigm; and the critical conflict view which treats any science as a professional group embedded within the wider political economy. The first two groups explain scientific change primarily in terms of processes intrinsic to the scientific group. For developmentalists, these processes are growth, differentiation and institutionalization; for Kuhnians, these processes are paradigmatic transformation and intragroup conflict. Critical conflict theorists argue that scientific change, though mediated by intragroup conflict, is caused primarily by processes extrinsic to the scientific group, specifically societal level changes in economy, class and ideology.

² Faris (1967:121) identifies the rebels as people who seemed to be "turning away from . . . traditional scholarly research . . . towards an active participation in national political and social controversy."

³ Martindale (1976:72-3) identifies the Young Turks as "restive young scholars" like George Lundberg, Donald Young, S. A. Stouffer, R. S. Lynd, Kimball Young, and F. Stuart Chapin.

⁴ Kuklick (1973:8) dismisses the quantifiers on whom Martindale focuses as "merely polemical" without "revolutionary consequences for American sociology."

Table 1. The Nature and Sources of Change in Contemporary Science:^a Three Approaches

The Issues	The Perspectives		
	Development	Kuhnian	Critical-Conflict
1. Illustrative writings ^b	Merton (1968), Parsons (1954), Ben-David (1970), Shils (1970)	Kuhn (1970), Hagstrom (1965), De Solla Price (1963), Friedrichs (1970)	Lukacs (1971), Gouldner (1970), McAulay (1978)
2. View of any science, as a social enterprise	A social system of roles and norms	A community of persons sharing a common identity and outlook, bound together by communication	An internally stratified professional group; a sector of the dominant class, located in a larger system of power, privilege and ideology
3. View of any science, as a body of ideas	Objective knowledge, theoretically formulated and empirically grounded	Interpretive systems, metaphors, paradigms	Substructures of ideology, superstructures of formal theory
4. Relation of (2) and (3)	Emphasis on (3)	Equal emphasis on (2) and (3)	Emphasis on (2)
5. Causes of change	Differentiation of the social system → logical-experimental advances in scientific investigation → convergences of ideas	Anomalies (tensions between theory and observation) → theoretical innovation → intra-community conflict and power struggle	Structural-ideological changes in society → intraprofessional power shifts
6. Outcome of change	Accumulation, sophistication, progress of knowledge	Outlook transformation, new norms for selecting and investigation problems	New relationship to society's power and ideological structures; change in science's potential for rational and critical knowledge
7. Distinctive features of the approach	Emphasis on idea continuity	Emphasis on idea transformation, incommensurability	Emphasis on the normative/ideological content of science
8. Guiding metaphor	The flowing stream	Political-religious revolutions	Marx's model of social organizations

^a Note the emphasis on *contemporary science*. These distinctions do not hold for views on the origins of science.

^b Since I am describing broad perspective, rather than close-knit "schools," the fit between these writings and these three perspectives is loose-knit rather than tight.

The various interpretations of the founding of the ASR reflect some of these more general differences in viewpoint. Faris relates both the causes and consequences of the episode to growth and differentiation within the profession. Kulkick works explicitly with themes of paradigm transformation and intragroup conflict. Martindale is less easy to type. His mention of sociology's response to the Depression brings in extrinsic factors which fit in with the critical conflict viewpoint, but his focus is on the confrontation between qualitative and quantitative methodologies, that is, on paradigm change. The last section of this paper attempts to evaluate the three general view-

points on scientific change explored in Table 1 in the light of the data presented in the main portion of this paper.

The Rebellion

The climax of the confrontation with Chicago and its journal occurred in the last week of December 1935 at the annual meeting of the ASS in New York City.⁵ The Society's Committee on Publications, chaired by W. P. Meroney of Baylor University, presented a proposal to the Soci-

⁵ Data in this paragraph and the next comes from the letter of Jerome Davis to Bernard, December 31, 1935.

ety's Executive Committee to establish the *ASR* as the official publication of the Society. Here the proposal, encountering strong opposition, was voted down 5:4. While my sources do not give a precise breakdown of the vote they identify William Ogburn and Herbert Blumer, both of Chicago, as major opponents of the proposal, and Jerome Davis of Yale as the chief fighter for it. The proposal then went as a minority report to the general membership at the business meeting. It was approved by a vote of approximately 2:1.

The rejection of Chicago went further. Hitherto the administration of the Society's affairs had been based at Chicago, and a member of that department had always served as secretary-treasurer of the Society. At the 1935 business meeting the membership approved the establishment of an independent executive office for the Society and elected a non-Chicagoan, Harold Phelps of Pittsburgh, secretary of the Society. A rebel sympathizer, F. H. Hankins of Smith College, was elected editor of the *ASR*, a second, H. P. Fairchild of New York University, was elected president of the Society. Stuart Rice, Chicago's candidate, withdrew his nomination in the expectation of humiliating defeat. Both elected vice-presidents were sympathizers with the anti-Chicago move, as were two of the six elected members of the Executive Committee. Two other elected executive committee members, Meroney and Davis, were prime movers in the rebellion. Only one elected committee member, Dorothy Thomas, an Ogburn loyalist, clearly can be linked to the Chicago cause.⁶ The rebels had effected significant organizational changes against Chicago, and had made an almost complete sweep of elected executive offices.

The confrontation at the 1935 meetings however does not constitute "the rebel-

lion against Chicago." At best it is the most striking episode in a five-year chronicle of sustained oppositional politics to Chicago by the anti-*AJS* rebels. The chief details of this are summarized in the Appendix. As shown here, the rebellion falls into three phases. The first (1931-1932) begins with the Parmelee letters (November 1931), and runs through the year of Bernard's presidency (1932) to the establishment of handpicked rebel committees on the issue of the *AJS* and on constitutional reform in the Society (December 1932). The second (1933-1934) is a period of rebel ineffectiveness and disorganization, and of effective counteraction by Chicago and its supporters. The third (1935), a time of renewed mobilization by the rebels, culminates in the confrontation at the December meetings.

Throughout the period, the focus of rebel attention is on Chicago's control of the Society. This they attack on a variety of fronts: in power struggles over the election of the Society's president, suggestions for reform of electoral rules, attempts to control the membership of both standing and special committees, suggestions for reorganization of the executive structure of the Society, and criticism of Chicago's influence on official publications of the Society. A degree of electoral reform is pushed through in 1933; administrative and publication changes are made in 1935. An important second issue for the rebels throughout the period is the question of what constitutes sound scientific research in sociology, how standards for this are to be set, and the relationship between this and the flow of research money into the profession.⁷ The questions of Chicago's centrality and of the criteria for scientific work are closely linked in the minds of the rebels. The implications of this linkage will be explored later.

The Combatants

Figure 1 shows the main groups in the 1931-1935 conflict. Certain char-

⁶ Elected vice-presidents were D. Sanderson of Cornell and Kolb of Wisconsin; the rebel sympathizers elected to the Executive Committee were J. Bosard of Pennsylvania and J. O. Hertzler of Nebraska. The sixth elected member of the committee, J. F. Steiner of Wisconsin, was probably also sympathetic to the rebels (Blumer in my interviews indicated that Wisconsin was on the whole hostile to Chicago's role in the Society).

⁷ For example, see Elmer to Bernard, March 3, 1932; Smith to Bernard; April 4, 1932; Floyd House to Bernard, April 6, 1932; Bernard to Davis, February 10, 1934.

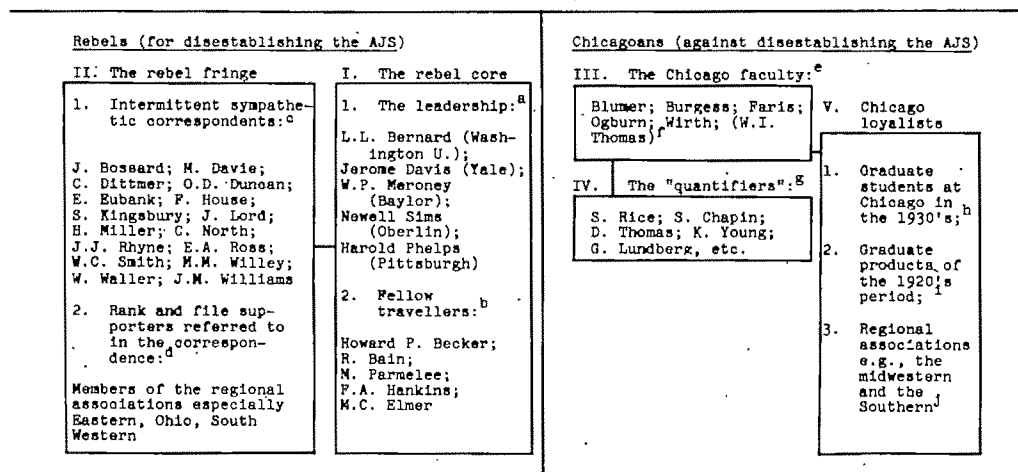

Figure 1. The Protagonists

^afor example: Meroney to Bernard, 1-21-32, 1-14-33; Davis to Bernard, many letters 6-33-11-33, Davis to Bernard, 1-2-34, 12-31-55; Sims to Bernard, 3-6-33, 3-20-33; Bernard to Meroney, 11-14-35; Bernard to Sims, 5-7-35; Report of the Committee to Consider a Plan for Control of the Official Journal, 12-33.

acteristics of each group deserve comment.

1. *The rebel leadership.* A small group, linked by years of collaborative political maneuvering, mounted the organized challenge to Chicago's associational centrality. Of these Bernard, Davis, Meroney, Sims and Phelps form the core group, a close-knit alliance. Bain, Parmelee, Becker, Elmer and Hankins, maintaining some distance from this central group, shared its hostility towards Chicago. On occasion they contributed to the formulation of strategy, but at other times they went their own way.

The characteristics of this group do not match those attributed to the AJS rebels by Kuklick, Martindale or Faris. Six of the ten men were over fifty in 1935, and

four had their highest degrees from Chicago⁸ in contrast to Kuklick's assertions. Their correspondence shows that they were not acting as a theory group, and none of the groups' members can be linked closely either to structural-functionalism (Kuklick) or to the quantification movement (Martindale). Despite Faris's claims, the group's members seem to have avoided social and political activism.⁹

⁸ Men over fifty, Bernard, Sims, Bain, Parmelee, Hankins, Elmer; Chicago products, Bernard, Meroney, Elmer, Becker.

⁹ Here, for example, is Bernard's position:

I believe no one could be more interested in making sociology of use to society, but . . . it seems to me much better to try to produce content to sociology and to orient ourselves with regard to

Most of the group's members had established professional reputations and long records of service in both the regional and the national organizations of sociologists.¹⁰ It makes no sense to see them as pursuing professional recognition or an associational niche by means of the rebellion.¹¹ It is important however to see them as "association men." This point is taken up later.

2. *The rebel fringe.* A large unorganized population, supporting the political maneuvers of the rebel leaders, fed them complaints and suggestions, and backed them on occasion in committee votes or in votes at the general business meetings of the Society. This population was strategic in the rebellion. Without its votes the leadership's action would have been ineffective.

Some of the members of this group are linked to the leadership by intermittent correspondence, but the larger part of these supporters can be known only indirectly by references to them in the correspondence and in my interview material. These data indicate first that discontent with Chicago's influence was spontaneous in this population; it was not simply created by actions of the leadership.¹² Second, this diffuse opposition did not share any particular theoretical outlook. It however was agitated and divided by

theoretical issues.¹³ Third, opposition was stronger in certain regions of the country than others, and was particularly strong in the Southwest and in the powerful eastern community.¹⁴ This opposition often found expression in the new regional associations which appeared in the thirties (Pease and Hetrick, 1977). The size of the vote for the rebels at the crucial 1935 meetings reflects the location of those meetings in New York City.

3. *The Chicagoans.* The organized opposition to Bernard's group is referred to in this paper as *Chicagoans*. In part this reflects the rebels' own sense of their protagonists as a single conspiratorial group whom they called "Chicago," "the Chicago group," "the Chicago machine." But close analysis of the content and authorship of the correspondence shows that political resistance to the rebels rested on a coalition between two groups. The first is the Chicago faculty, notably Faris, Wirth, Burgess, Blumer, and Ogburn, who closed ranks in defense of their department's long-standing position in the ASS. The second group contains most of Martindale's Young Turks: Rice, Chapin, Lundberg, Kimball Young, and Dorothy Thomas.¹⁵ Members of both groups held important executive positions in the Society during the period,¹⁶ and their actions

our problems of research than it would be to attempt to be useful to a group of men who are dominated by a viewpoint that is almost wholly unscientific [i.e., the present political organizations]. (Bernard to Kingsbury, May 4, 1932)

¹⁰ Careful study of Odum, a most valuable source book on the personalities of the period makes this clear.

¹¹ The exceptions may be Meroney, whose reputation was established by his flamboyant actions against Chicago, and Parmelee, who established links to the eastern and national societies by his actions.

¹² For example:

We face the pent-up dissatisfactions of ten years. These have been growing without definite form and without leadership. . . . [T]he dissatisfaction in our ranks is so great that even he [Parmelee] was able to bring us last year . . . close to open revolt . . . [W]e found unanimous and vigorous dissatisfaction with the "old order" in the American Sociological Society. . . . [Y]ou were really elected . . . on that issue. (Dittmer to Bernard, February 27, 1932)

¹³ For example:

I have a feeling that we are sitting on a mine, and may, have an explosion that will blow the A.S.S. into four or five regional bodies, and two or three or four "Schools" who will continually be at each other's throats: the statistical group, the McIver-like mystics, the case-study attitude boys, the reformitarian-community "organizers," the social work fellows. (Bain to Bernard, March 23, 1932)

¹⁴ See Bain's statement, above. Also interview with Herbert Blumer.

¹⁵ W. I. Thomas is seen by the rebels as an ally of the Young Turks (Bernard to Davis, February 10, 1934; Bernard to Bossard, March 1935).

¹⁶ Burgess (1934) and Chapin (1935) were presidents of the ASS during the period, and Rice was Chicago's nominee for the presidency for 1936; Wirth and Blumer between them covered the role of secretary-treasurer of the ASS continuously over the period; Faris edited the *AJS*; Rice chaired the influential Committee on Research which acquired the task of looking into the issue of constitutional reforms in 1932; Ogburn and Rice, together with W. I. Thomas, were the Society's Research Planning Society, 1934-1935.

from this base are consistently antagonistic to the Bernard group.¹⁷ The degree of active cooperation between the two groups varies over the period, but in 1935 the "quantifier," Rice, was in line for the presidency of the Society and was viewed by the rebels as Chicago's candidate. In 1936, in the aftermath of the 1935 rebel victory, members of both groups founded the SRA (interviews with Blumer, Cottrell).

A coalition between Young Turks and the Chicago faculty seems improbable only if, first, we see them as two irreconcilable theory groups (quantifiers and a qualitatively oriented Chicago School); and, second, if we assume that theoretical affiliation is the dominant factor in professional cooperation and division. I address the first assumption here, and the second in the next section.

In the thirties the Young Turks were a theory group, a movement passionately proselytizing for radical positivism and for quantification as a means to that end. Chicago, however, was not a School. Its reputation for theoretical cohesion among contemporaries and later writers reflects its situation in the twenties, with Park's centrality and the visibility of his Research Institute of productive, talented graduate students. Even this group in this earlier period, moreover, was in no way theoretically opposed either to positivistic directions for sociology or to quantification.¹⁸ By the thirties the Chicago department had become a melange of theoretical positions, prominent among which was that represented by Ogburn. Ogburn (1929) was the prophetic spokesman of the quantifiers, many of whom had been his students either at Columbia or at Chicago. The theoretical divide between the two

groups thus is not as watertight as it has been depicted.

4. *The Chicago loyalist.* Like the rebel fringe this is a population which we can discern only dimly and inferentially in the correspondence. Figure 1 identifies the main groups in this population. Many of its members were Chicago products, though this in itself was no guarantee of loyalty, as the ranks of the rebels show. Others seem to have been deterred as much by the acrimoniousness of the rebels' style as by the content of their message. In the end the support of this population proved ineffective in preserving Chicago's position.

The Context and Issues

Five factors, in interaction, produced the rebellion.

1. *Personality and biography.* Both the correspondence and my interview material show that various long-standing animosities, a generalized sense of grievance, and the vagaries of short-tempered personalities helped produce the rebellion.¹⁹ This tells us part of the story of the organized opposition, a little about the timing of the episode, and nothing about the wider disaffection. A fuller explanation requires that we consider the social characteristics of the period.

2. *Professional expansion.* During the twenties there had been a significant increase of graduate programs and Ph.D.s in sociology (Chapin, 1934; Bernard, 1945). Such growth implies differentiation of interests, and this in turn makes increasingly difficult the organizational hegemony which Chicago had established in earlier times.

3. *Changes at Chicago.* The fund of internal cohesion and morale which had sustained Chicago's organizational influence in the twenties was considerably depleted by the thirties. Park's aging and retirement, growing awareness of theoretical problems in the 1920s framework (Kuklick, 1973), differentiation of interests in the department (Faris, 1967; Shils, 1970), in-fighting over theoretical dif-

¹⁷ This is particularly evident in Rice's opposition to Bernard's push for constitutional reform on the Committee on Research 1932, and Chapin's opposition to Bernard's move to disestablish the *AJS* in 1935.

¹⁸ The Park and Burgess (1921:44) text saw the mission of the 1920s era in American sociology to be that of achieving empirical precision for the discipline and the whole development of the ecological research effort at Chicago was precisely an effort to achieve precision through quantification.

¹⁹ All interviewees mentioned Bernard's personal feud with Faris.

ferences (interviews with Blumer, de Vinney, Lejins) all helped produce this change. Personalities and the changes at Chicago ([2] and [3]) in combination probably made a challenge to Chicago's influence inevitable. But to understand the rebels' motives and perceptions, the patterns of coalition and division in the conflict, and the formulation of the issues, one must draw on the interaction between factors (4) and (5).

4. *The quantification challenge.* A major conceptual shift occurred in American sociology in the thirties: the move to center stage of a methodology based on large-scale quantification. This methodology rested on theoretical assumptions about a social universe which was massive, structured, patterned, predictable and empirically knowable. It was fired by an ideology of radical positivism which called for full mobilization of the profession in pursuit of objective knowledge about the causal principles of social life, and which advocated, as means to this end, standardization of research procedures, team research, statistical sophistication. This ideology was moreover radically elitist on the issue of what activities constitute "good" sociology (Ogburn, 1929).

This new orientation was promoted by an identifiable theory group, originating in the so-called Columbia group of the twenties (Bernard, 1973; Wiley, 1978). From the twenties Ogburn was the group's leading luminary (Bernard, 1973). His move to Chicago in 1927 broadened the regional base of the quantifiers. His presidential speech in 1929 was a platform speech for their perspective.

During the thirties this group expanded to include Ogburn's converts at Chicago (e.g., Stouffer) and the students of other members of the Columbia group (e.g., Lundberg at Minnesota). The quantifiers, moreover, clearly were moving to positions of centrality in the profession: into executive positions in the Society; into committees controlling research funds; and into the burgeoning structure of policy-related jobs in the New Deal administration.²⁰

²⁰ Ogburn, Chapin, Rice and Dorothy Thomas all

Bernard's rebels resisted the quantifiers not so much on theoretical grounds,²¹ but in terms of their growing power base in the profession and their militant but narrow definition of what constituted good sociology (Bernard, 1932). Most significant of all, given our interests, the rebels assumed that they were observing a process by which this new theoretical-ideological elitism fused with the organizational elitism which had for so long given Chicago centrality in the profession. They assumed, that is, that the Chicago faculty and the quantifiers were a working coalition.²²

Several observations led to this assumption of coalition: Ogburn's position as a ranking member of the Chicago department and as the mentor and inspiration of the positivists; his election to the presidency by tactics which seemed a prime example of Chicago's tendency to political railroading and his presidential

had executive positions in the Society over the period; Rice, Ogburn and Lundberg had positions on the Social Science Research Council; Ogburn and Rice were influential in the New Deal's effort to utilize social science.

²¹ Theoretical opposition to the quantifiers was mounted by McIver (1931; 1942), Sorokin (1936; 1944), Znaniecki (1934). Chicago's public stance against the methodological position of the quantifiers was cautious and ambivalent (Blumer, 1931; 1939).

²² This important point emerges from the following statements:

[1.] Although I received my Ph.D. from Chicago I feel that the dominance the Chicago group has exercised in the Society has been harmful, and the linkage of Ogburn and Rice seems to me to augur the continuance of that domination. (Becker to Bernard, October 5, 1932)

[2.] . . . [I]n my own thought Ogburn has played the role of the villain in the drama of American sociology for several years. . . . [H]e is the leader and prophet of those who are disposed to deny the title of science to everything but statistics . . . and . . . from his position in the Social Science Research Council he is able . . . to have considerable influence on the public affairs of organized social science. (House to Bernard, April 6, 1932)

[3.] I am sure we shall have a difficult job before us to thwart the designs of the Ogburn-Rice machine. Incidentally, I learned . . . that the Chicago group has the whole FERA under their thumb in Washington. . . . They are thus in a very strategic position. It is typical of the close working of that Chicago machine. (Sims to Bernard, April 8, 1935) Also Bernard to Davis, February 10, 1934; Davis to Bernard, 1934 (undated); Bernard to Bossard, March 1935; Parmelee to Bernard, April 1935.

address which symbolically opened the quantifiers' campaign; Stuart Rice's chairmanship of the Society's Special Committee on the Scope of Research, during which he worked both to block efforts toward electoral reform which would have challenged Chicago, and to advance the quantifiers' view of scientific sociology; Chapin's election to the presidency as the quantifiers' candidate and his subsequent coolness to Bernard's suggestions for a new journal; W. I. Thomas's link to the quantifiers through his wife, and his support of them on the Social Science Research Council. One could multiply such illustrations. Together they led the rebels to see a functioning coalition between Chicago and the quantifiers on research committees, government panels, annual elections in the Society, committees for constitutional change, and in defense of the *AJS*. When one adds the fact that the theoretical debate over the quantifiers' position which did occur at Chicago (interviews with Herbert Blumer, Leland de Vinney, Peter Lejins) was confined within the walls of the department and not aired before the society, the rebels' sense of an elitist conspiracy is even more understandable.

The idea of conspiracy was an exaggeration. What there was between the Chicago faculty and the quantifiers was a degree of spontaneous unanimity in political action, as well as a degree of more self-conscious cooperation. An interplay of several factors produced this: the personal links already described; theoretical ambivalence in the classic Chicago position on the positivist issue raised by the quantifiers; norms of loyalty among Chicago products and of civility among its faculty; active dislike of Bernard and some of his associates by members of both groups; the commonality of interests that exists between elites, and their tendency to rally against a challenge to the principle of elitism. In 1936, in the aftermath of the rebellion, these same factors led Chicago and the quantifiers to found the SRA.

5. *The Depression*. In several specific ways the massive international crisis of the Depression deepened the lines of division in the sociological community.

(a) Theoretical strain. The Depression

presented sociologists with a dramatic new set of empirical problems for theoretical interpretation, problems which were massive, societal, international. The Park and Burgess (1921) framework, with its focus on intraurban group dynamics, was unsuited to this theoretical task. The theoretical fragmentation which occurred at Chicago in the thirties, perhaps even its declining ability to command a wide professional audience, derives in part from this situation (Lengermann, 1977). At the same time the fervor of the quantifiers during the thirties (though not the origins of that movement) can be traced to the Depression. The cry for better science and greater technical proficiency, the attack on existing sociology as too "philosophical," expressed the quantifiers' frustrations over the discipline's inability to respond to the crisis, and their strategy for a more effective response (Ben-David, 1970; Martindale, 1976). In the early thirties there were many sociologists at least half persuaded by this appeal.

(b) The survival of the *AJS*. The Depression strengthened the determination of the Chicago faculty to head off the rebellion, for in a time of economic hardship it was feared that the journal might not survive without the guaranteed market provided by the Society's membership. This threat led men of varied theoretical outlooks to close ranks in defense of the journal (interview with Herbert Blumer).

(c) The regional associations. These organizations were products of the thirties, more inexpensively providing a forum for professional activity than the national association. Between 1929 and 1932 the ASS lost 25% of its membership (interview with Herbert Blumer). Many of these financially precarious sociologists probably joined the regionals. As we shall shortly see, many of them resented Chicago's professional centrality. The regionals, as noted earlier, became organizational structures for consolidating the sense of disaffection from Chicago.

(d) Career anxiety. The Depression halted and then reversed the expanding career structure for sociologists in universities, leading to cuts in salaries and in the number of positions (Chapin, 1934; Faris, 1934; Johnson to Bernard, January 18,

1932). Some sociologists were safe, untouched by the crisis. These were persons with high-ranking positions, in well-endowed schools, and with strategic locations in the networks of communication and influence that impinge on university careers. But for recent Ph.D.s, or persons of junior rank, in small schools, with small professional reputations, the Depression posed a constant threat. Some were forced to drop out of the ASS by financial hardship, others probably hung on precariously to their membership. For all of them competition became intense for survival in existing jobs, for new employment opportunities, and for the professional recognition that enhances career chances. Anything that smacked of a calculated narrowing of access to these opportunities roused hostility and resentment. And these threats seemed to be present in Chicago's particularistic, inner-circle pattern of job recommendations, its editorial control over what was published in the *AJS*, its influence on what was selected for presentation at the Society's annual meetings, its influence on who could gain prominence through executive service to the profession, its inner track to research money, and, with the shifting pattern of opportunity that came with the New Deal, its access to an elaborating structure of government jobs (letters to Bernard from Smith, April 4, 1932; from House, April 6, 1932; Duncan, April 29, 1932; Sims, April 8, 1935; Bernard to Reinhardt, December 19, 1933). Indeed, given the rebels' perception of a coalition between Chicago and the quantifiers, the situation of the thirties seemed to pose a rapidly growing threat to career chances. For the older situation of organizational control by Chicago went along with a broad and eclectic definition of what constituted "good" sociology. The emerging new situation, however, seemed to augur the linkage of this old pattern of control to a narrow and rigid definition of professional achievement (Smith to Bernard, April 4, 1932; House to Bernard, April 6, 1932). This situation of competition and anxiety produced the rank and file supporters of the rebellion.

In summary the rebellion that disestablished the *AJS* occurred in a situation of

organizational diversification in the profession and of declining cohesion at Chicago. The rebellion was led by men who often had personal grievances against Chicago and supported by a population who, because of the Depression, resented Chicago's influence on career chances in sociology. Both leaders and supporters believed that there were rapidly growing elitist trends in the profession. Leaders and followers were bound together, not by a theoretical viewpoint, but by an organizational ideology of antielitism.

The Consequences

The 1935 episode marked the peak in the mobilization of Bernard's rebels. While continuing to be vigilant for their interests, there was a reduction of interest, a shift to new issues.²³ The economic crisis was fading away. The leaders, aware that they made significant gains in their effort to reduce Chicago's organizational centrality, may have been content to reduce their level of commitment.

The organizational changes produced by the rebellion did not result in the full egalitarian system which its leaders had talked of at the height of the contest, and which their opposition had dreaded. It did however extend opportunities for effective participation and influence in the national society to groups not sponsored by Chicago, in particular to eastern-based sociologists. The Eastern Conference was the single most powerful regional association, after the Midwestern; its support had been strategic to Bernard's effort. It was the center for the public debate on the theoretical implications of the quantification movement and it had a density of structure and effort which contrasts with some of the other areas which had supported the rebellion. This density proved an effective resource in the drive to seize the opportunities created by the 1935 rebellion.

This is particularly true with regard to the new journal. As Chicago continued to monopolize its *AJS*, the new *ASR* func-

²³ Bernard's attention shifts to the American Association of University Professors in the years immediately following 1935.

tioned increasingly as a forum for eastern-based sociology. Since the rebels were not a theory group, their imprint on the *ASR* is not a discernible one. Instead one sees the patterns of the paradigmatic contest being waged in the East—between quantifiers, their critics, and, increasingly, the emerging perspective of structural-functionalism.²⁴ In this sense both the quantifiers and structural-functionalists were heirs of the rebellion. Neither quantifiers nor structural-functionalists, however, had made the rebellion.

Conclusions

The thirties were a period of rapid, significant change in American sociology during which many of the structures of the contemporary profession were institutionalized. These include the particular pattern of influential journals which channel professional communication, some important organizational features of the professional society, sociology's particular service relationship to national public policy, the centrality of a method based on large-scale quantification, a theoretical focus on macrosystems, and the centering of professional influence in the Northeast. What caused these changes? My introduction described three competing perspectives in contemporary sociology on the issue of scientific change. This section looks at the degree of "fit" among these approaches and the episode of scientific change described in this paper.

1. *Perspectives emphasizing intrinsic factors for scientific change.* (a) The developmentalists. This group sees structural differentiation as a major change process in scientific systems. Differentiation refers to a relatively steady increase in organizational complexity, resulting in part from increases in group size. This paper has not focused on such processes, but has touched on some factors which indicate their occurrence: multiplication of graduate departments of sociology,

"overproduction" of Ph.D.s, differentiation between the aspirations of the graduate departments and those of smaller schools, the emergence of regional groups, a greater diversity of sources of research support, a greater number of formal theoretical alternatives, multiplication of journals, and greater organization complexity in the ASS. Some of these changes (those named first) are antecedent conditions for others (those listed later). In a way which is classic to the developmentalist model, differentiation begets differentiation and is both cause and content of the process of change. There is a fit therefore between this approach and the particular change episode I have described. Alone, however, differentiation is an inadequate explanation of the episode, telling us little about the acceleration of change in the thirties, the motivations of the participants, or the specific outcomes of the episode.

(b) The Kuhnians. This perspective focuses on processes of theoretical stress, theoretical change, and professional conflict in explaining scientific change. These processes describe the main features in the case study described in this paper. The decline of the Park and Burgess perspective, the challenge of militant quantifiers, the later emergence of structural functionalism, these theoretical changes frame the episode, which is in itself one of fierce professional conflict. But Kuhnians fuse theoretical change and professional conflict into a single change process in which theoretical issues have causal priority. In this case study we see that theoretical challenge and professional infighting were partly independent of each other. The cautionary note that must be raised on the basis of this study is as follows: scientific communities do divide and fight over paradigms. They also divide and fight over issues of professional power, status and material privilege. These two sources of confrontation may fuse into a single dynamic for conflict, but they are not necessarily fused.

2. *Perspectives emphasizing extrinsic factors for scientific change: the critical conflict perspective.* This perspective looks to changes in the broader societal context of the profession for the main

²⁴ Hence Kuklick's interpretation of the sources of rebellion. She uses the *AJS* and the *ASR* as her primary data.

causes of scientific change. My paper has focused on one element of change in American society which influenced the sociological community: the Depression and New Deal.²⁵ The societal crisis of the thirties raised new empirical and theoretical questions for sociologists, brought new demands from public and state to bear on the professional community, opened up new sources of employment and research support, created career anxiety for many sociologists and helped produce the regional associations which became bases for opposition to Chicago. At a concrete level it fuelled the processes of theoretical change and of intra-professional conflict. At an abstract level it demonstrated the openness of the boundaries between society and a discipline which claims that its special focus is society. The Depression however is not *the* cause of the changes in sociology in the thirties. Theoretical transformation, underway before 1929, was prompted both by the growth and differentiation of the profession, and by the growing recognition of theoretical and methodological problems in the Park and Burgess Chicago framework. Similarly many of the factors which would lead to a fight over Chicago's centrality were present before the Depression years: personal feuds, Chicago's loss of momentum, professional differentiation, and emerging elitist coalitions. The Depression accelerated the rush into open conflict in the ways indicated above. It was both one cause and a major precipitating factor for the changes of the thirties in American sociology.

What does this case study of scientific change tell us about the three models of scientific change in contemporary sociology? It shows that each is a partial model, each exaggerating, by exclusive focus, the independent causal status of one cluster of explanatory factors. A full explanation of scientific change requires that one look at the relationships among these factors. An abstract statement about the nature of these relationships must await an accumulation of case studies of the type reported here.

²⁵ Though the critical conflict theorists would emphasize economic and political changes like the De-

APPENDIX

THE REBELLION AGAINST CHICAGO

I. *Prologue*

Dec. 1928	Ogburn's election as president of the ASS
Dec. 1929	Ogburn's presidential address—platform speech for radical positivism
1930	(Gap in correspondence)

II. *The First Rebel Thrust (January 1931–December 1932)*

Jan. 1931	Correspondence on abuses in ASS electoral procedures ^a
Spring 1931	Anti-Chicago discussions, led by Maurice Parmelee, at Eastern Sociological Conference ^b
Nov. 1931	"Three Communications from Dr. M. Parmelee," <i>AJS</i> 37:3, p. 468. In name of ad hoc committee of eastern sociologists' proposals for: (i) electoral reform in ASS (ii) review of current scientific standards in sociology
Dec. 1931	Rebel political action: (i) L. L. Bernard elected president of ASS ^c (ii) establishment of a committee to consider a plan for control of the official journal ^d (iii) expansion of the functions of the Special Committee on the Scope of Research by the ASS (the "Rice Committee," funded by SSRC to report to ASRC) to consider Parmelee issues of scientific standards and electoral reorganization ^e
Jan.–Nov. 1932	Constant struggle between Bernard and "establishment" on: (i) committee chairmen, esp. Finance Committee; Bernard makes inroads ^f

pression, my own view is that these are only some of the significant societal changes that influenced American sociology in the thirties. Almost as important, for example, is the reorientation of philosophy towards logical positivism and the transposition of these ideas to America in the thirties with the intellectual migration from Nazism (Toulmin, 1977; Fleming and Bailyn, 1969).

^a Letters by Bernard, dated Jan. 8 and Jan. 12, 1931.

^b Dittmer to Bernard, Feb. 27, 1932.

STRUCTURAL DETERMINANTS OF URBANIZATION IN ASIA AND LATIN AMERICA, 1950-1970*

GLENN FIREBAUGH
Vanderbilt University

American Sociological Review 1979, Vol. 44 (April):199-215

Why is the world becoming increasingly urban? The primary reason is economic development, but economic development alone is inadequate for explaining urbanization in the Third World. Theoretical arguments and fragmentary empirical evidence suggest that, in the underdeveloped regions of Asia and Latin America, urbanization is caused by adverse rural conditions as well as by economic development. Data for 27 Asian and Latin American nations in 1960 and 1970 provide evidence that two rural conditions, high agricultural density and plantation agriculture, spur urbanization in underdeveloped regions, independent of the effects of economic development and prior urbanization in these regions.

The world is becoming increasingly urban. In 1850, 2% of the world's population lived in cities of over 100,000; in 1900, 6%; in 1950, 16%; in 1970, 24% lived in cities of that size (Davis, 1972: chap. 3). The present historical epoch, then, is marked by population *redistribution* as well as by population *increase*. The consequences of this redistribution—this "urban transition" from a predominantly rural, agricultural world to a predominantly urban, nonagricultural world—are likely to be of the same order of magnitude as those of the more widely-heralded increase in world population.

This paper examines the determinants of urbanization in underdeveloped nations in Asia and Latin America. In the industrial West, the urban transition was an adjunct to the industrial revolution; as a consequence, as McGee (1971:201) noted, students of western urbanization often have viewed urbanization as virtually in-

separable from economic development. These students often wheeled in the finely-tuned machinery of traditional economic theory to account for the widely-documented relationship between urbanization and industrialization. Stated briefly, this view holds that industries, seeking to overcome the friction of space in the interchange of goods, locate in contiguous areas. This creates demand for labor in concentrated spatial areas. To attract this needed labor, higher wages are offered in urban areas. Since labor moves (it is hypothesized) from areas where it earns a lower return to areas where it earns a higher return, this urban/rural wage differential results in urban growth. Eventually, however, the labor movement results in an equalization of the marginal productivity of urban and rural labor; the wage difference then vanishes and migration ceases. In short, migration "plays the role of equilibrator . . . in an ideal homeostatic process" (Berliner, 1977:456); migration is a contributor to development, a corrector of regional imbalances, and a conqueror of the "tyranny of space" (for an excellent literature review which takes this position, see Spengler and Myers, 1977).

The cheerfulness of this *labor adjustment* view of urbanization has been muted, particularly among students of urbanization in the Third World, by a growing recognition of the adverse reasons for and effects of urbanization (for a literature

This paper uses data I collected for my dissertation. I am indebted to the members of the committee—Phillips Cutright (chairman), Elton Jackson, Daniel Maki (mathematics department), and David Snyder—for their advice and encouragement in that enterprise, and to Indiana and Vanderbilt Universities for computer access. I would also like to thank Carolyn Style for her assistance in transforming the data to a form readable by the Vanderbilt computer, and the anonymous *ASR* reviewers for helpful comments on an earlier version.

review see Shaw, 1976: chap. 1).¹ Current tendencies to see urbanization in a less favorable light are spurred by evidence which is difficult to reconcile with the previous view: economists puzzle over the continuation of rural-urban migration in the face of very high rates of unemployment and underemployment in Third World cities (Todaro, 1977: chap. 9); geographers speak of the role of "population pressure on resources" in stimulating rural-urban migration, independent of industrialization in the Third World (see the selections in Zelinsky et al., 1970), and others discuss the role of various rural institutions in prompting rural-urban migration (Thiesenhusen, 1971; Shaw, 1976); social scientists of various disciplines note the extreme magnitude of urban squalor in many parts of the Third World (for example, Hauser, 1957; Breese, 1966; Jackson, 1974; Davis, 1975).

How are we to account for the divergence between the urbanization experience of many underdeveloped nations and the beneficent product promised by labor adjustment theory? For labor adjustment theory, the most disconcerting feature of Third World urbanization is the persistence of rural-urban migration in the face of urban unemployment. Todaro (1969; Harris and Todaro, 1970) suggested that this apparent incongruity could be explained by introducing a stochastic element in the wage difference: Todaro postulated that migration is determined by *expected*, rather than actual, wage differences, where these expected differences take urban employment probability into account. While this modification is useful (the Todaro model currently is the predominant urbanization model in macroeconomics), it stops short of specifying the objective structural reasons for the rural/urban wage differentials.

In this paper I argue that the structural causes of urbanization in the Third World

are embedded in rural strictures as well as in urban attractions. This contention is not new; much of the urbanization literature emphasizes the effect of shrinking rural opportunity on urbanization.² Hard evidence for this popular view is scarce, however. Indeed, most empirical cross-national studies have concluded that adverse rural conditions have no effect on urbanization.

This paper uses data for 27 Asian and Latin American nations at two points in time (1960 and 1970) to assess the independent effects of rural conditions on urbanization. We first examine the theoretical basis for the contention that adverse rural conditions, as well as economic development, prompt urbanization in the Third World. As noted above, most empirical cross-national studies of this contention have concluded that adverse rural conditions have no effect; however, a review of the methodology of these studies casts doubt on their findings. The data used here do not permit a thorough examination of all the relevant hypotheses about the effect of rural conditions on urbanization; nevertheless, the results support the thesis that two key rural characteristics, agricultural density and type of land tenure, have significant effects on urbanization. The final section of this paper discusses the implications of this finding for urbanization theory.

RURAL CONDITIONS AND URBANIZATION IN UNDERDEVELOPED NATIONS

If one makes the reasonable assumption that adverse proximate conditions are more likely to prompt migration than promising distant conditions,³ then the

² Adverse rural conditions could affect urbanization in developed countries as well as in underdeveloped countries. Accumulating evidence suggests that conditions such as enclosures and the commercialization of agriculture were indeed factors in early western urbanization (Hobsbawm and Rudé, 1968). I will note the differences between urbanization in developed and underdeveloped countries in a later section.

³ Proximate conditions are better known than distant conditions to the potential migrant. Further, experienced adversity may be more effective than the promise of prosperity in overcoming the "property of inertia" (Berliner, 1977:447) in human behavior, though of course we can only speculate on this point.

¹ In general sociologists have been less enthusiastic about urbanization than economists, since sociologists typically have focused on social structural and social psychological effects of urbanization (Wirth, 1938, for example; also Fischer, 1972), while economists typically have focused on the role of urbanization in moving labor from the primary to the (more productive) secondary sector.

price of millet may well be more important in rural-urban migration than the going urban wage. In this section we will explore in some detail the possible links between adverse rural conditions and urbanization in underdeveloped nations.

Level of urbanization (that is, percent urban) can change because of (1) net urban in- or out-migration, (2) reclassification of area (that is, due to population increase and/or annexation, an area previously classified as nonurban can be reclassified as urban), or (3) differences in urban and rural rates of natural increase.⁴ The discussion in this section will focus on the theoretical rationale for expecting rural conditions to affect urbanization through their effect on rural-urban migration and urban/rural fertility differentials.⁵ While rural-urban migration and urban/rural differentials are distinct conceptually, they are confounded empirically; rural-urban migration likely affects the urban/rural fertility differential (see below). We now look in more detail at these links between rural conditions and urbanization;

we examine first the migration link, then the fertility differential link.

Rural-Urban Migration: Direct Effect

The overwhelming reason for the increase in percent urban in the Third World is (net) rural-urban migration. Population movement from rural to urban areas obviously increases percent urban, since it increases its numerator without changing its denominator. This is the direct effect of rural-urban migration on urbanization (as distinct from its indirect effect, that is, its effect on the urban/rural fertility differential). Here I sketch the logic behind the premise that rural conditions in the Third World independently contribute to urbanward population movement.

In underdeveloped nations adverse rural conditions often stem from rapid population increase. Rural populations can respond to rapid population growth in three ways: emigration (movement to urban areas), frontier development (cultivation of additional land), and/or agricultural involution (further subdivision of presently-cultivated land). According to many observers, emigration is a common response (for example, Hauser, 1957; Jackson, 1974; Munro, 1974). The ability to make a living in most rural areas in the Third World is tied to the availability of arable land. Where agricultural density is high and families are large, farmers cannot always afford to subdivide the land for their children. Additional land must be brought under the plow; but such land is not always available. Under such circumstances some of the population will be displaced and will migrate to cities.⁶ Indeed, according to Long (1975:3), "The inability of subsistence agriculture to absorb such a large increase in the rural population has resulted in a refugee-like movement of large numbers of persons to the only available haven, the cities."

⁴ Focussing on urban/rural differentials *by themselves*, we would expect percent urban to decrease in underdeveloped nations, since in these nations rural rate of natural increase typically exceeds urban rate (Martine, 1975)—that is, the urban/rural ratio is typically less than one. Since percent urban is increasing in these nations, we can infer what has been documented more directly: the presence of extensive rural-urban migration.

Along these lines, several readers of an earlier draft misinterpreted the meaning of a positive effect. To say that adversity of rural conditions affects the urban/rural differential in natural increase in a positive direction is *not* to say that percent urban would necessarily *increase* in the absence of urban in-migration or reclassification—that is, it is not to say that the urban/rural ratio will necessarily exceed one in regions characterized by adverse rural conditions. Rather a positive effect means that, in two regions alike in other respects, we expect the region with the more adverse rural conditions to have the larger urban/rural ratio, albeit this ratio will likely still be less than one.

⁵ I do not expect rural conditions to be related to urbanization through reclassification; indeed, reclassification is a type of measurement error resulting from the fact that one must set a criterion for classifying an area as urban. I do not expect this measurement error to bias the results, however. Reclassification accounts for a relatively small fraction of city growth (about 7% worldwide for 1960–1970: Davis, 1972:314). In addition, there is little reason to believe that reclassification is related to the independent variables.

⁶ This is not to say that emigration is the *exclusive* response to population increase in underdeveloped nations (see Boserup, 1965, and Kumar, 1973, for evidence of frontier development; see Geertz, 1963, for evidence of agricultural involution in Java). While a given individual does not respond in all three ways simultaneously, a population can: some farmers may emigrate, some may work new land, some may subdivide the land they have.

Besides rapid population increase, Third World agriculture is characterized by structures which generate and perpetuate inequality (Beckford, 1972; Kocher, 1973). The Spanish colonization of Latin America is a classic example: large land grants to early colonizers led to a system dominated by the *latifundista*. The effect of this system is still evident in much of Latin America. In Colombia in 1960, for example, .6% of the farms contained 40% of the total agricultural land, while 63% of the farms contained less than 5% of the land (Shaw, 1976:Table 5.1). It is generally conceded that such institutional arrangements promote the use of capital-intensive techniques (Dorne, 1972: chap. 4) and permit the use of large proportions of a nation's land (often its best land) for food and nonfood export crops even in the face of insufficient national foodstocks (Lappe and Collins, 1977). In addition, some argue that these arrangements exacerbate inequality as large landholders stand to benefit much more than small landholders from imported technology (Barraclough and Schatan, 1973). The effect of land tenure structures on capital-intensive vs. labor-intensive techniques is particularly relevant to migration; *ceteris paribus*, we would expect greater inequality to lead to greater emigration through its promotion of capital-intensive techniques. I will be unable to speak directly to all these points in the data analysis, since cross-national land tenure data are crude, but I did want to note the grounds for believing that agrarian structures affect rural-urban migration.

Developed countries. Does the above *rural push* argument also apply to the historical experience of presently "developed" countries? Developed countries of course also experienced rapid population increase as they passed through the demographic transition. In addition, there is evidence that rural structures drove people from the land in these countries as well (Hobsbawm and Rudé, 1968). However, a consideration of both sides of the squeeze—population increase vs. urban and rural economic expansion—suggests that the squeeze is more severe in the case of the underdeveloped countries.

Rates of population increase in underdeveloped countries exceed those experienced by developed countries. In the Third World, birth rates exceed death rates, often substantially, in urban areas as well as in rural areas. Hence underdeveloped countries, in contrast to the experience of developed countries (Bairoch, 1975:155), must contend with substantial migration to cities which are already growing rapidly due to natural increase *per se*:

When the migrants come, as they inevitably do in substantial numbers, they therefore come on harsh terms. . . . Their number is large enough, added to excess births, to push city growth beyond any rate hitherto known. . . . (Davis, 1973:222)

Further, circumstances in the developed countries differed in that, during their period of rapid population growth, the New World was available as a population outlet (Trewartha, 1969:chap. 2). Finally, population density of the developed countries was lower at the outset; taken together the underdeveloped countries exhibit a density five times that of the developed countries at a comparable level of urbanization (Davis, 1973).

While rate of population increase in the underdeveloped countries has exceeded that experienced by the developed countries, economic expansion has not (Todaro, 1977:chap. 8). In spite of the positive growth rates found in most underdeveloped countries (Todaro, 1977:Appendix 2.2), few if any of these countries have been able to duplicate the experience of the West in which, after some lag (Jones, 1971), industrialization produced rapid expansion of urban employment opportunities. This difference between underdeveloped and developed countries stems largely from their differential positions in the world economy, as dependency theory emphasizes (for example, Wallerstein, 1974). In particular, dependency theory argues that the economic dependence of the underdeveloped peripheral countries on the core capitalist powers distorts the economic, political, and social structures of the peripheral countries (Beckford, 1972; Chase-Dunn, 1975). Put very briefly, economic dependence results in the interrelated problems of (1) highly-concentrated economic growth and (2)

importation by the periphery of (inappropriate) capital-intensive technology from the core (see the selections in Wilber, 1973); such highly-concentrated, capital-intensive economic growth has not been conducive to the expansion of urban or rural employment in underdeveloped countries (Todaro, 1977:chap. 8).⁷

In sum, support can be found for the view that adverse rural conditions contributed to urbanization in the developed as well as the underdeveloped countries. But the effect is likely much greater in underdeveloped countries, where the population and economic constraints are more severe: population growth is faster and aggregate economic growth is not being effectively translated into employment for the masses.⁸

Urban/Rural Fertility Differentials

Adverse rural conditions can affect urbanization by prompting rural-urban migration. The effects of migration can be indirect as well as direct: migration can affect the urban/rural differential in natural increase—specifically, the fertility differential⁹—which, as we noted above, affects urbanization. Friedlander (1969) discussed the relationship between migration and fertility in developed nations; in this section I will discuss this relationship in underdeveloped nations. Finally, I will consider the possibility that adverse rural

conditions affect urban/rural differentials independent of the direct and indirect effects of migration.

How could migration affect the urban/rural fertility ratio? Consider first the baseline case where migrants are randomly selected from their areas of origin. Assume further that, in the Third World, rural natives have higher fertility than urban natives (a proposition which is generally accepted). In such a case, migration (in either direction: rural natives to cities or city natives to rural areas) would narrow the gap between urban and rural birth rates; that is, migration would increase the urban/rural fertility ratio.

However, the assumption that migrants are randomly selected is erroneous (Lee, 1966); if the spate of microdemographic migration studies have a central message, it is that migration is selective with respect to certain individual characteristics. The most important of these characteristics is age; migrants are more likely to be of childbearing age (Weller et al., 1971). Like the argument in the baseline case, the selection-by-age argument implies a narrowing of the urban/rural fertility gap in underdeveloped nations. On the other hand, selection on the basis of other characteristics could work to inflate the fertility gap. In particular, rural migrants may be selected on the basis of traits related to social mobility, which traits tend to be inversely related to fertility. However, selection on the basis of mobility traits is probably more important in early, development-induced migration, and is less important in migration prompted by adverse rural conditions (Zarate and Zarate, 1975:150).

In short, the relationship between migration and the urban/rural fertility ratio is somewhat ambiguous: some characteristics would tend to raise the ratio, others would tend to lower the ratio. However, the weight of the evidence favors the view that the former dominate; that is, the *net* effect of migration most likely is to raise the urban/rural fertility ratio. Most likely, then, the indirect effect of migration on urbanization, like the direct effect of migration on urbanization, is positive. Further, the indirect effect of migration no doubt is small relative to the

⁷ The point is *not* that core nations eschewed all capital-intensive technology in their early industrialization but rather that for them such technology was indigenous.

⁸ What about the effect of rural conditions on urbanization in developed countries *now*? In a separate cross-national analysis (Firebaugh, 1976:chap. 5) I found that agricultural density has no effect on urbanization in western developed countries, 1950–1970. However, proxy measures of constraints on demand for agricultural products did have positive, independent effects on urbanization. This finding was consistent with the expectation that present constraints in the agricultural economies of developed countries involve aggregate demand and not land.

⁹ Firm evidence concerning mortality differentials is lacking (United Nations, 1973:135). Consistent with most of the previous literature (for example, Macisco and Myers, 1975), then, I will focus this discussion on fertility differentials.

direct effect of migration; indeed, in the Third World, migration *per se* no doubt is a far more potent factor in redistributing population than is differential natural increase.

One question remains in our consideration of the links between rural conditions and urbanization: Do adverse rural conditions (directly) inhibit rural fertility (thereby increasing the urban/rural fertility ratio)? The possible effect of density on urban fertility has attracted a great deal of attention (see Galle and Gove, 1978, for a literature review), while the effect of agricultural density on rural fertility virtually has been ignored. This is ironic, since a high level of density is a more acute economic problem in rural areas than in urban areas; farming is more land-extensive than industry. High agricultural density would tend to reduce the value of children's production, *ceteris paribus*; according to the microeconomic view of fertility, this would reduce fertility (see, for example, Williams, 1976). Evidence from the Punjab suggests that high agricultural density may indeed inhibit rural fertility (Ali, 1979). However, I must stress that this evidence is preliminary; definitive conclusions cannot be made at this point.

What can we conclude about rural conditions and urbanization on the basis of the theoretical considerations and fragmentary empirical evidence reviewed above? Figure 1 depicts the intervening variables, and the expected signs, in the relationship between rural conditions and urbanization. The effect of adversity on

urbanization through migration is positive; the direct effect of migration on urbanization is positive, and likely substantial; the indirect effect of migration on urbanization probably is also positive, but smaller. The direct effect of adversity on the urban/rural differential is unknown; however, even if, contrary to the Punjab evidence, it is negative, this effect surely would not offset the positive effects of adversity which operate through migration. I would like to be able to estimate all the coefficients in the path diagram in Figure 1 but, given the scarcity of migration and rural- and urban-specific fertility data for most of the Third World, such partitioning of effects must be left to future studies. We must be content with a more limited objective: to assess the *net* impact of rural conditions on urbanization in the Third World. For this more limited objective the implications of Figure 1 are clear: we expect the net effects of adverse rural conditions on urbanization to be positive.

METHODOLOGY

Unit of Analysis

Properties such as urbanization and agricultural density describe regions, not individuals. What type of region (province? nation? continent?) is most appropriate for studying determinants of urbanization? On the one hand, the larger the region, the fewer the cases (that is, the less efficient the analysis). On the other hand, regions should be large enough to encompass most rural-urban migration;

Figure 1. Path Diagram Depicting the Intervening Variables, and the Expected Signs, in the Relationship between Rural Conditions and Urbanization

between-region migration can distort the effects of the independent variables. Suppose, for example, that agricultural density does stimulate rural-urban migration, but that much of the migration is from high density to low density regions. In this case, the relationship between agricultural density and urbanization across regions would understate the actual effect of agricultural density.

The unit of analysis in this study is the nation. This unit is not perfect, but it has two important advantages. First, national boundaries often act as barriers to migration, and most rural-urban migration is internal to nations. Second, the most comprehensive data are available at this level. We want data for Asia and Latin America; since land constraints (due to high agricultural density and/or unequal forms of land tenure) are most severe there, this is the area where adverse rural conditions are most likely to affect urbanization (Hauser, 1957; Shaw, 1976). Reasonably reliable data on urbanization, economic development, and land constraint are available for almost all this area, if we use nations as the unit of analysis.

Deficiencies in Previous Studies

Empirical studies of the effect of rural conditions on urbanization in underdeveloped nations have yielded mixed, and controversial, results. Consider agricultural density (measured by farmer/land ratio), for example:

Our findings support the common-sense argument that a population's response to high agricultural density from increasing population is to cultivate the land more intensively rather than to abandon agriculture and move to urban areas. (Kumar, 1973:210)

[T]hat there is no positive correlation between rural pressure and urbanization has . . . been conclusively demonstrated. (Bussey, 1973:5)

The cross-national analyses of Sovani (1964) and Kamerschen (1969) support this view.

Others, however, have as confidently attested to the importance of agricultural density for urbanization in underdeveloped nations: "[T]hroughout Southeast

Asia the overwhelming cause of rural-urban migration is the existence of a stagnating rural economy typified by land shortage" (Jackson, 1974:25). The cross-national analyses of Davis and Golden (1954) and Long (1975) are substantially consistent with this view.

Why these discrepancies in findings? Methodological deficiencies cast suspicion on many of these findings (Firebaugh, 1976:chap. 1). Some researchers have pointed to the nonsignificant or negative *bivariate* relationship between agricultural density and percent urban as inconsistent with the land constraint thesis (Sovani, 1964; Kamerschen, 1969: 240). Such a conclusion is tenuous, since the bivariate relationship between agricultural density and percent urban neglects the confounding influences of important variables such as economic development. In addition, both bivariate and multivariate analyses of rural push are flawed by poorly defined sampling universes. Analyses of the effect of agricultural density on percent urban have included developed as well as underdeveloped nations. Since we do not expect agricultural density currently to affect urbanization in developed nations (see above), including developed nations would likely camouflage effects of agricultural density.

As remedies for these deficiencies, this analysis (1) employs a regression model of urbanization which includes controls for economic development and nation-specific historical and geographical factors, and (2) restricts the sample to underdeveloped nations in Asia and Latin America.¹⁰

¹⁰ Various empirical criteria have been advanced for identifying underdeveloped nations but none has gained universal acceptance. For this analysis I used Mexico as the cutoff point: nations at or below Mexico's level of economic development (as measured by the economic index used in this analysis) were considered underdeveloped. These nations are Afghanistan, Bolivia, Brazil, Burma, Ceylon, China, Columbia, Cuba, Dominican Republic, Ecuador, El Salvador, Guatemala, Haiti, Honduras, India, Indonesia, South Korea, Mexico, Nepal, Nicaragua, East Pakistan, West Pakistan, Paraguay, Peru, Philippines, Thailand, Turkey. Nations with no rural populations, as well as very small nations and principalities, were omitted. Desert nations were ana-

Overview of the Model

The general form of the model of urbanization is:

$$U = f(E, R, H-G), \quad (1)$$

where U refers to urbanization, E to economic development, R to rural conditions, and $H-G$ to nation-specific historical and geographical factors. Since one does not expect their effects to be immediate, the independent variables were lagged ten years. Other lag lengths were tried; however, since structural conditions such as economic development are highly correlated across time, the estimates differ little over these alternative specifications.

The model is applied to underdeveloped nations in Asia and Latin America for the period 1950–1970. The choice of 1950–1970 was dictated by the fact that rural population increase in these nations has been especially rapid since about 1950 and by the absence of reliable data on agricultural density before 1950. The data are by decades: 1950, 1960, and 1970. Data for shorter intervals are not available for many of the variables; even if they were, due to the stability of these variables over short periods of time, little analytical leverage would be gained by collecting more observations in the 1950–1970 interval (Hannan and Young, 1977). The analysis, then, is based on 54 cases: 27 nations, each at two points in time (1960 and 1970 for the dependent variable, 1950 and 1960 for the other variables).

Like most panel analyses in sociology, this analysis is based more on covariance across units than across time; stated differently, the analysis is more cross-sectional than longitudinal. Cross-sectional analyses of nations are especially susceptible to spurious findings stemming from the different histories and geographies of nations. For example, Lieberman and Hansen (1974) showed that, while economic development and language diversity are inversely related across nations, they are unrelated across time within nations. They interpreted this

discrepancy in terms of the historical circumstances surrounding nation formation: newer nations tend to be both less developed and less able to design their national boundaries to coincide with language boundaries. This is a particular illustration of a general moral: Cross-national analyses can yield seriously misleading results due to uncontrolled historical and geographical factors, while time-series studies in effect can “control” these factors by focusing on units with constant geographies and histories. In cross-sectional analyses, then, it is important to include controls for these factors.

Measurement of Variables

Secondary analyses of cross-national data are beset with difficulties. Difficulties attend data collection (for example, the problem of data comparability across nations) as well as data analysis (for example, nonlinearities). Secondary analyses can be especially vulnerable to error introduced in data collection: decisions made at that stage cannot be recovered completely, while data analysis problems often can be, if not sidestepped, at least evaluated (see below). Fortunately, data collection problems have been minimized for the present study by Kingsley Davis and his associates at the University of California-Berkeley's International Population and Urban Research center, whose careful efforts have yielded comparable cross-national data on the two key variables in this study: urbanization and agricultural density. The remaining data are primarily from United Nations sources; where possible these were cross-checked with other sources. I judge, then, that the study undertaken here is quite reasonable, particularly since the theses being tested specify only the direction of effects and not their exact size. We now look at the measures in more detail.

Urbanization. Since our interest here is the predominant character (urban vs. rural) of a region and not its number of urban residents, our dependent variable is percent urban.¹¹ Data for “urban areas”

lyzed separately (Firebaugh, 1976). Cambodia, Laos, Vietnam and North Korea were omitted because of inadequate data.

¹¹ If we were interested instead in the determinants of number of urban residents in a nation, an

(the political city plus adjacent suburbs) are used where possible, thereby reducing measurement error due to annexation. I chose 100,000+ as the criterion for "urban" in this analysis (from Davis, 1969: Table C); as we will see later, basic conclusions are unaffected by the use of another cutoff point.

Economic development. Economic development is measured by an index formed by summing per capita annual energy consumption (in terms of kilograms coal equivalent; from United Nations, 1929ff) and number of telephones per capita (from Banks, 1971, and American Telephone and Telegraph, 1972); these were standardized to unit variance before summing. Energy consumption is closely tied to the aggregate capacity and actual output of an economy. However, I want the index to reflect the distribution of production as well as its aggregate level since, as noted above, highly concentrated growth has been ineffective in generating urban employment opportunities for the masses in the Third World. I selected telephones to measure this distributional aspect of economic development, since others (for example, Cutright et al., 1976) have argued that a wealthy elite is unlikely to "overconsume" telephones. However, I found, as many others have, that various measures of economic development (GNP, energy consumption, telephones, etc.) are so highly correlated across nations that results are not dependent on the particular economic measure selected.¹²

Rural conditions. Agricultural density, the number of farmers relative to land under cultivation, is commonly used as a measure of land constraint (Kamerschen, 1969; Kumar, 1973; Long, 1975). The numerator used for this person-land ratio

is the number of males in the agricultural labor force; the exclusion of females is necessitated by the failure of most countries to report female participation in agriculture. As Kumar (1973) argued, the denominator of this measure should not include all rural land but only that which is under tillage or lying fallow. The measure of agricultural density used in this analysis, therefore, is number of agriculturally employed males per square kilometer of arable land (taken from Kumar, 1973). Table 1 gives the mean agricultural densities of nations in selected regions. Since this measure is skewed to the right (skew=1.4), it was transformed by the natural logarithm (skew=-.2). Unfortunately, agricultural density data are unavailable for four of the 27 nations (eight of the 54 cases); however, as we will see below, this apparently does not affect the results.

Since the amount of land required to support a given number of farmers can vary from nation to nation, agricultural density per se is an incomplete indicator of population pressure. Soil quality, topography, rainfall, and length of growing season all affect the carrying capacity of land. In addition to such natural resource differences, nations can differ on social organizational and technological factors related to agriculture.

Besides agricultural density and land tenure, then, I included the following measures of rural conditions in a preliminary analysis (not reported here): agricultural mechanization, agricultural produc-

Table 1. Mean Agricultural Density of Nations: Selected Regions, 1950 and 1960^a

Region	N	Agricultural Density	
		1950	1960
Asia ^b	11	87.1	90.5
Latin America ^b	13	50.6	49.4
Europe	22	29.5	25.6
North America	2	3.4	2.3
All Developed Nations	34	28.1	23.7

Source: computed from Kumar, 1973: Appendix Table VII.

^a Agricultural density is number of agricultural workers per square kilometer of arable land. The means reported are not weighted by size of nation.

^b Developed countries excluded.

analysis without ratio variables would be preferable: in such a case national population should be used as an independent variable, not as a denominator (Schuessler, 1974).

¹² The energy+telephones index was skewed to the right and nonlinear with respect to urbanization. The best transformation, in terms of reducing skew and producing linearity, is $(\ln [\text{index}])^2$, where \ln is the natural logarithm function. This is the transformation used in the results reported here; parallel analyses using other transformations yielded similar results.

tion (agricultural gross domestic product, in constant U.S. dollars, divided by agricultural population; from Food and Agricultural Organization, 1971b: Annex), and production instability (an index of fluctuations in agricultural production, 1952–1972; from F.O.A., 1974:141). I expected agricultural mechanization to have a positive effect on urbanization, since mechanized agriculture requires less labor. I found, however, that agricultural mechanization and economic development are so highly correlated that measures for the former are superfluous. I selected agricultural production as a proxy for natural resources (collecting and coding cross-national data on resources like soil quality and drainage characteristics would require a herculean effort); with measures of amount of land per farmer (agricultural density), agricultural technology, and land tenure already in the model, effects of agricultural production should be due predominantly to cross-national differences in natural resources. Finally, I reasoned that, where production is uncertain, farmers—rich or poor—may emigrate (indeed, complete crop failures may leave farmers with little choice). Contrary to expectations, neither production level nor production stability affected urbanization in a consistent manner.

Cross-national data on land tenure are so crude that I could do no better than classify nations by their predominant form of land tenure. I relied on two sources for this classification: where possible, the 1960 World Census of Agriculture (Food and Agricultural Organization, 1971a); otherwise, Adelman and Morris (1967). The 1960 census of agriculture included data on size and type of land holdings. Adelman and Morris used experts to categorize nations according to their predominant form of land tenure. From these data I was able to construct four categories: owner-operated, tenant- or renter-operated, communist, and plantation. These were entered in the model as dummy variables.

Historical and geographical effects. Idiosyncratic characteristics or experiences of a given nation may facilitate or impede urbanization. These characteristics may be historical (colonial ex-

periences, for example) or geographical (presence of natural harbors, for example). As we noted above, such effects must be controlled in cross-sectional analysis.

Realistically one cannot quantify geographical and historical conditions directly. How then does one control such effects? Note that geographical and historical factors (1) typically are long-standing national features and (2) likely are more important to initial urbanization than to later urbanization. Indeed, we might expect most of the effects of geographical and historical conditions on 1960 and 1970 urbanization to be mediated by earlier urbanization. This suggests prior urbanization as a control for geographical and historical effects on urbanization.¹³ I selected 1930 urbanization (from Banks, 1971) for this purpose (reliable data on urbanization are unavailable before then for some of the nations).

FINDINGS

Each of the 27 nations has data at two points in time, so the analysis consists of 54 cases. Since there is no theoretical or empirical reason to believe the parameters are different in 1960 and 1970, I combined (pooled) the cross-sectional and time-series data. Pooling increases the accuracy of the estimates (Hannan and Young, 1977). Pooled data are of the general form:

$$Y_{it} = \alpha + \beta X_{i,t-k} + \epsilon_{it} \quad (2)$$

¹³ For general discussions of controlling for prior levels of the dependent variable as a means of avoiding spurious effects, see Heise (1970) and Carlsson (1972). Liberson and Hansen's (1974) proposal for handling cross-sectional bias—to control for date of national independence—is tantamount to controlling for prior levels of the dependent variable since, in their case, date of independence is highly correlated with prior levels of the dependent variable.

Cross-sectional bias could be averted here in two other ways. First, I could include dummy variables for nations, thereby controlling for *all* nation-specific effects (Firebaugh, forthcoming). However, this approach would require 26 dummy variables, with the result that the number of parameters to be estimated would be uncomfortably close to the number of cases. Second, I could use change variables. However, employing change variables is inadvisable here since it would (1) halve the number of cases, leading to a severe loss of efficiency, and (2) magnify measurement error (Bohrnstedt, 1969).

where Y_{it} is the value of Y for the i^{th} unit at time t , $X_{i, t-k}$ is the value of X for the i^{th} unit at time $t-k$, and k is the length of the lag. In this analysis, i =nation 1, nation 2, . . . , nation 27; t =1960, 1970; and k =10 years. Note also that in this analysis the dependent variable at a previous point in time is included as an explanatory variable. Hence the model used here is a type of panel model (Heise, 1970). The use of panel analysis is often advocated in cross-national research as a means for reducing the possibility of "simultaneity bias" due to reciprocal effects (Chase-Dunn, 1975; Delacroix and Ragin, 1978).

Table 2 presents zero-order correlations between the variables used in this analysis. Observe first the correlates of the dependent variable. As expected, urbanization is highly correlated with prior urbanization and economic development; economic development alone accounts for roughly two-thirds of the variance in urbanization. Urbanization is *negatively* correlated with agricultural density ($r = -.32$). This is not surprising, since other studies report a negative relationship. The zero-order correlations also tell us that, in this population, communist nations and nations characterized by plantation agriculture are more urban than those where the majority of farms are owner-operated or tenant. Turning now to the correlations between independent variables, we can see that economic development and ag-

Table 3. Determinants of Urbanization in Asia and Latin America, 1960 and 1970 (Pooled)

^b Adjusted for degrees of freedom.

ricultural density are negatively related ($r = -.60$). Note also that, compared with many cross-national analyses, the correlations between the independent variables generally are small; only two exceed 1.51. Hence multicollinearity is not a problem here.

Table 3 presents the independent effects of prior urbanization, economic development, and rural conditions on urbanization.¹⁴ Economic development has by far the largest effect, but agricultural density, prior urbanization, and plantation agriculture also have nontrivial positive effects on urbanization. These four variables account for nearly three-fourths of the variance in urbanization. The other forms of land tenure (communist, owner-operated, tenant) have no independent effects on urbanization.

^c Correlations based on 46 cases.

^d Dummy variable: yes=1, no=0.

¹⁴ Ordinary least squares regression was used here and in the tables which follow (except where noted otherwise). Assuming no autocorrelation of the residuals, OLS is the recommended estimator in models which incorporate lagged Y among the explanatory variables (Johnston, 1972:306-7). Unfortunately, the assumption of no autocorrelation of ϵ could not be assessed empirically, since conventional tests for autocorrelation are not appropriate in models containing lagged Y values (Johnston, 1972:309). This assumption appears reasonable here, however, since (1) the data are predominantly cross-sectional and (2) prior urbanization was included for the purpose of controlling for the very types of effects which would result in autocorrelation of the residuals. If this assumption is wrong—that is, if ϵ is autocorrelated—then the effect of prior urbanization will be overstated while effects of variables positively correlated with prior urbanization will be understated (Hannan and Young, 1977). This bias would not affect estimates of the effects of rural conditions, however, since these are minimally correlated with prior urbanization ($r^2 = .09$ between agricultural density and prior urbanization: Table 2).

In short, the results from the additive model are consistent with the thesis that adverse rural conditions affect urbanization independent of economic development.

Interaction Model

Do prior urbanization, economic development, and rural conditions have the same effect on urbanization in Asia as in Latin America? The additive model above assumes that they do. But we may question this assumption, particularly with respect to agricultural density. In addition to rural-urban migration, rural populations can respond to rapid growth by frontier development and by involution (see above). In general, opportunities for the agricultural labor force, short of emigration, appear greater in Latin America than in Asia. Since alternatives to migration may be less available in Asia, the effect of agricultural density on urbanization may be greater there.

I examined these possibilities by using a model with regional interaction terms—that is, terms which allow for the effects to differ between Asia and Latin America. Table 4 reports the results. The interaction model fits slightly better than the additive model (note the R^2 's). More important, the expected interaction effect appears for agricultural density: the effect of agricultural density is greater in Asia

than in Latin America ($b = 3.3$ vs. 2.4). In addition, the effect of prior urbanization differs by region: it is inconsequential in Asia, but not in Latin America. However, no interaction effect appears for economic development. Finally, as in the additive model, the only form of land tenure to affect urbanization is plantation agriculture. All these effects are statistically significant at the .05 level or better.¹⁵ We now consider each of them in more detail.

Economic development. Numerous cross-national studies report a large positive *bivariate* relationship between urbanization and economic development. Table 4 indicates that this relationship remains very strong even with controls for rural conditions and prior urbanization. Hence these results support the view that economic development and urbanization are closely tied, though they do not support the view that economic development is the sole determinant of urbanization.

Prior urbanization. 1930 urbanization was employed as a proxy for nation-specific historical and geographical factors which affect urbanization. In particular, one expects colonial policy to have an abiding effect on urbanization. Both Asia and Latin America were colonized extensively. However, 1930 urbanization has no effect on recent urbanization in Asia, and surprisingly little effect in Latin America ($\beta = .20$). The bivariate relationship between 1930 urbanization and recent urbanization ($r = .66$) is severely attenuated by controls for economic development and rural conditions. Apparently the recent urbanization of Asia and Latin America is more dependent on contemporary factors than on the historical experiences of nations.

Rural conditions. Plantation agriculture has a positive effect on urbanization in these nations. In two nations alike in economic development, prior urbanization, and agricultural density, we expect percent urban to be higher by 3.3 in the nation dominated by plantation agriculture ($b = 3.3$; since plantation agriculture is a dummy variable this is not a slope but rather an increment to the y-intercept).

Table 4. Determinants of Urbanization in Asia and Latin America, 1960 and 1970 (Pooled): Interaction Model

^a Estimated by two-stage least squares employing the following simultaneous equation model:

$$U_t = f(E_t, D_{t-10}, \text{prior urbanization, plantation agriculture});$$

$$E_t = f(E_{t-10}, U_t),$$

where U refers to urbanization, E to economic development, D to agricultural density, and t to 1960, 1970.

^b Transformed (see text) and lagged ten years (except in reciprocal effects model).

^c Transformed (see text) and lagged ten years.

^d Trivial.

Agricultural density also has a significant, positive effect on urbanization. This effect is greater in Asia than in Latin America. Since these findings about rural conditions are contrary to the findings of most previous studies, we examine their robustness under still other specifications.

Other Specifications

I respecified the model in a number of ways to gauge the stability of the estimates.¹⁶ The respecifications yielded results consistent with those of the baseline models of Tables 3 and 4. Table 5 reports results for specifications motivated by the comments of reviewers. One's conclu-

sions are the same whether one compares the metric or standardized coefficients; in Table 5 I follow convention and report the metric coefficients. In the first respecification, the eight cases with missing data are excluded (Listwise Deletion: Table 5). Note that the coefficients for this model are consistent with those of both baseline models, the additive model (top panel, Table 5) and the interaction model (bottom panel, Table 5). The results, then, do not depend on the method of handling missing data. In the second respecification (Year Controlled) I included a dummy variable for year. Under this specification the coefficients are *within-year* slopes (Duncan et al., 1961:65-6, 166-8). Again, the estimates barely differ from those of the baseline models.

As noted above, panel analysis is often advocated as a means of reducing the possibility of bias due to reciprocal effects. This method is not foolproof, how-

¹⁶ I also used scattergrams to check nonlinearities, outliers, etc., in both the zero-order and partial relationships, and found no problems in the variables as transformed.

ever (Hannan and Young, 1977).¹⁷ To check for simultaneity bias, I employed simultaneous equation models; these estimate reciprocal effects directly. Feedback effects from urbanization to economic development and agricultural density seem possible; feedback effects on land tenure system and prior urbanization seem unlikely. I began, then, with a simultaneous equation model which allowed for reciprocal effects between urbanization and economic development, and urbanization and agricultural density. Two-stage least squares estimates were β (standardized regression coefficient) = .08 for the effect of urbanization on economic development and β = .0002 for its effect on agricultural density. Obviously the feedback effect of urbanization on agricultural density safely can be ignored; this permits a simpler model (since agricultural density need not be treated as endogenous) with urbanization and economic development as the endogenous variables (Table 5, note a). Table 5 (Reciprocal Effects) reports the two-stage least squares estimates for the urbanization equation in this model. These estimates show no significant departures from previous results, albeit the effects of economic development and rural conditions are slightly attenuated. Finally, I examined the effects

of rural conditions on an urbanization measure which includes urban areas smaller than 100,000. I again used data from Davis (1969:Table C); these data are based on urban areas as defined by each nation (typically at least 2,000). The final column in Table 5 reports estimates for the additive and interaction models applied to this more inclusive measure of urbanization. The effects of economic development and plantation agriculture are greater in this case, while the effects of prior urbanization, and agricultural density in Asia, are smaller. Nevertheless, the basic pattern of effects remains. In short, the alternative models provide further support for the contention that agricultural density and plantation agriculture have independent, positive effects on urbanization in underdeveloped nations in Asia and Latin America.

DISCUSSION

The overarching conclusion of this analysis is that a theory of urbanization of underdeveloped nations must take into account conditions on the farm as well as conditions in the city. Specifically, we found that agricultural density and plantation agriculture affect urbanization in the underdeveloped nations in Asia and Latin America.¹⁸

Can we conclude from this finding that Asian and Latin American nations are overurbanized—that is, more urban than warranted by their level of economic development? (That Asian and Latin American nations are overurbanized is a popular contention in demography, geography, ecology, and political science, as well as in sociology; see Bairoch, 1975: chap. 8, and Firebaugh, 1976:chap. 1.) The land constraint thesis is indeed a key plank in the overurbanization argument (Sovani, 1964). Rural-urban migration due to land constraint, however, is not a sufficient condition for overurbanization; we should

¹⁷ In panel analysis the lag length of the dependent variable is typically the same as that of the other variables. Using different lag lengths, as here, could make one more susceptible to simultaneity bias. However, bear in mind that in this analysis prior urbanization is used not only as a hedge against simultaneity bias but also as a measure of nation-specific factors which affect urbanization. I used 1930 urbanization because I judged early urbanization to be a purer measure of these nation-specific factors. In any case, I examined the effect of prior urbanization under various lag lengths. As one would expect, the shorter the lag the larger the effect attributed to prior urbanization; the additive effect of 1950 urbanization, for example, is $b = .81$ (as opposed to .35; Table 3). Using 1950 urbanization reduces the estimate of the effect of economic development (from .71 to .43); the estimates for agricultural density and plantation agriculture are barely affected. Other lag specifications for urbanization followed this pattern—that is, shorter lags increased the estimates for prior urbanization and decreased the estimates for economic development—but in all cases the estimates for economic development, plantation agriculture, and agricultural density were positive and nontrivial.

¹⁸ I do not expect an amelioration of these conditions in the near future, particularly in view of the relative neglect of agriculture in the development programs of many underdeveloped countries (see Lipton, 1977, for a detailed discussion of the urban bias present in development strategies of underdeveloped countries).

not assume that push migration (that is, migration stemming from deficiencies in the rural sending areas rather than from the attractions of the urban receiving areas) necessarily leads to a harmful imbalance between level of urbanization and level of economic growth. First, empirical tests for imbalance between level of urbanization and level of economic development have faltered in that they have been unable to determine the "proper" balance between urbanization and economic development. Second, even if sociologists could show that rural push leads to an imbalanced condition between urbanization and economic development, such evidence would not demonstrate that unfortunate urban conditions in underdeveloped nations are solely or substantially attributable to this imbalance (overurbanization theory alleges that imbalance between urbanization and economic development is a principal contributor to urban woes in underdeveloped nations: see Hauser, 1957:chap. 2). Further analysis would be needed to eliminate alternative hypotheses. Third, note that the alternative to overurbanization may be worse than overurbanization. If the "excess" people do not reside in urban areas, then they must reside in nonurban areas. Overpopulation in rural areas may well be more detrimental to a nation than overpopulation in urban areas (Keyfitz, 1965:290).

CONCLUSION

Economic development is no doubt the most important determinant of urbanization. The findings of this analysis imply, however, that urbanization theory should focus on rural as well as urban conditions. Ideally, a theory of urbanization would apply both to developed and to underdeveloped nations. I suggest that this is possible in a theory which incorporates (1) the sources of rural constraints (increasing population? form of land tenure? increasing scale of agriculture?) and (2) the alternatives to rural-urban migration. Developing such a general structural theory of urbanization is the logical next step in the study of the urbanization of nations.

MANUSCRIPTS FOR THE ASA ROSE SOCIOLOGY SERIES

Manuscripts (100 to 300 typed pages) are solicited for publication in the *ASA Arnold and Caroline Rose Monograph Series*. The Series welcomes a variety of types of sociological work—qualitative or quantitative empirical studies, and theoretical or methodological treatises. An author should submit three copies of a manuscript for consideration to the Series Editor, Professor Robin M. Williams, Jr., Department of Sociology, Cornell University, Ithaca, New York 14853.

VALUES, DISTRIBUTIVE JUSTICE AND SOCIAL CHANGE*

IRVING TALLMAN AND MARILYN IHINGER-TALLMAN

Washington State University

American Sociological Review 1979, Vol. 44 (April):216-235

Principles drawn from the exchange perspective are combined with generalizations drawn from bargaining, coalition and prisoner dilemma research to explain the effect of social structural conditions on collective values emphasizing material attainment vs. interpersonal satisfactions and norms of equality vs. norms of proportionality. The theory is applied to issues of social development. Materialistic values are predicted for poor and developing societies and interpersonal satisfaction values are predicted for industrialized societies. The theory also predicts that norms of equality and solidarity are more likely to develop in societies with simple class structures and norms of proportionality are more likely to develop with increasing structural complexity. Data from a study of Mexican and U. S. parents and their children are presented to support hypotheses drawn from the theory. Some of the criticisms of exchange theory as a basis for explaining the formation of social norms are examined and the utility of the theory's underlying individualistic and utilitarian assumptions are explored and defended.

Despite their growing popularity, exchange theories have had limited application as a basis for sociological explanations of social change (see, for example, Kuhn, 1974:427-46). This absence may be due to the inability of exchange theorists adequately to account for development and change in social values and norms. This is a formidable obstacle since values and norms have been interpreted consistently as either determinants or consequences of social development and change (Kahl, 1968; Inkeles, 1966; Rogers, 1969; Foster, 1967; Nash, 1967).

Although most exchange theorists view norms as critical in delimiting the types of rewards and costs acceptable in social exchanges, the processes by which such norms are formulated and altered frequently are viewed as external to the theory (Homans, 1961:115; Meeker, 1971; Cook, 1975; Blau, 1964:253-63; Thibaut and Kelley, 1959:127-30; Heath, 1976:50-74, 154-60). Even the attempt by Berger et al. (1972), to explicate carefully the structural aspects of distributive justice norms resorts to stipulating a "re-

ferential structure" whose source is unknown. Cook and Emerson (1978), using an exchange perspective, present data indicating that equity concerns place constraints on the use of power. Although the experiment they report provides specific structural conditions under which equity concerns will be expressed (e.g., imbalanced power relationships and knowledge of other's outcomes), the emergence of the equity norm itself is not explained, but rather is treated as a given amenable to activation under the specified conditions.¹ The fact that norms are culturally transmitted does not, in our view, serve as an explanation for their generation or demise (see Kuhn, 1974:431). What is needed is the specification of principles pertaining to the emergence of specific norms and the conditions under which transmissions occur.

Those who question the utility of the exchange perspective often point to its failure to deal effectively with issues of social order and social control. Moreover, this failure frequently is attributed to the individualistic and utilitarian assumptions

¹ In a footnote, Cook and Emerson, however, do differentiate between proportional and equality formulations of equity and suggest that the latter are more likely to occur in two-party exchanges, whereas the former are more applicable when third parties play a role in distributing resources. This formulation is similar but not identical with the propositions we shall develop later in this paper.

underlying this perspective² (Ekeh, 1974; Heath, 1976; Buckley et al., 1974). "Morality," to paraphrase these critics, "cannot be explained on the basis of individual self-engrandizement."

Reports by Komarita and Chertkoff (1973) and Bonacich (1970; 1972; 1976), however, are suggestive of ways in which individualistic and utilitarian assumptions can combine with other exchange principles to explain norm formation and change within collectivities. Komarita and Chertkoff report that group norms pertaining to the distribution of rewards can be predicted from knowledge of the distribution of resources within a given group. Bonacich, in a series of studies in which the prisoners' dilemma situation is expanded to four-, five-, and six-person groups, has shown that when the dilemma is most pronounced (i.e., the conflict between individual benefits and collective well-being is greatest), norms of group solidarity are most likely to develop and be enforced. Both of these sets of findings suggest a relationship between structural conditions, perceived self-interest, and the development of social norms. More specifically, as we shall see below, the two sets of findings suggest a relationship between the distribution of resources, norms of equality or proportionality pertaining to such distributions and norms of group solidarity.

In this paper we shall use principles drawn from the above works within the exchange paradigm to explain how desig-

nated social structural conditions affect: (1) the value placed on life goals by members of a collectivity; and (2) the norms of distributive justice which evolve. The hypotheses developed are tested against data gathered in Mexico and the United States. Finally, the findings are related to current debates about the utility of exchange theory for explaining social change.

THEORETICAL FRAMEWORK

Our point of departure is an assumption which underlies most exchange and rational-choice models. We assume that human actors are satisfaction seekers and will choose those courses of action which, based on the information they have available, will increase their chances of attaining the benefits they desire at the least possible cost.³ Also implicit in the exchange perspective is the assumption that desired benefits are scarce and, therefore, people often are forced to choose between potentially satisfying goods. Such choices depend, in part, on actors' preferences (values) and, in part, on actors' subjective estimates of their chances for acquiring the desired goods (Camilleri et al., 1972). Since the goods people seek are obtained through transactions within the social structure, we infer that the two key variables—values and subjective probabilities—result from actors' perceptions of the opportunities available to them in the social structure to conduct favorable transactions. Our first task is to examine how the social structure influences the decision process. We then shall identify those elements in the structure

² Some exchange theorists respond to this criticism by denying the necessity for these assumptions (see Emerson, 1976:345-7). This is particularly true of those who rely heavily on principles drawn from operant psychology (Emerson, 1972; 1976; Homans, 1961). Space does not allow for a detailed discussion of this orientation as compared with exchange theories which draw more heavily on an economic model (Blau, 1964:168-86). To avoid an overly long explanation, we shall merely state that we are in agreement with Heath (1976:3) that implicit in the exchange perspective is the notion that actors make rational choices in exchange situations. This does not imply, however, that human beings consider the contingencies or follow the complex calculations depicted by decision and game theorists. Rather it implies that, within the social and personal constraints individuals have for making decisions, they make them in ways which they believe will be to their benefit (see Kuhn, 1974:115).

³ This assumption is essential not only to the theory developed here, but to most exchange, decision, game and coalition theories (see Heath, 1976:7-50). The assumption also is the basis for the criticism that the exchange perspective leads to tautological arguments in which "any action can be said to maximize someone's gain" (P. S. Cohen quoted in Emerson, 1976). We attempt to avoid this obvious danger by specifying structural conditions which are hypothesized to lead to adherence to specific values and norms. The assumption, as well as the exchange perspective, in our view is best understood as elements in a paradigm that provide a framework for building theories. The utility of the exchange perspective (and its underlying assumptions) can best be evaluated by assessing the utility of the theories it generates.

which influence the formation of values and norms of distributive justice, the latter representing some means of controlling the probability of outcome. The opportunity must exist for actors to initiate and respond to offers to engage in exchanges. Emerson applies the term *exchange relations* to such opportunity structures. These exchange relations continue over time and can be extended to include networks which connect actors to one another either socially, psychologically, or geographically. Every actor in an exchange network, however, is not necessarily connected with every other actor. All actors, therefore, do not have the same opportunities to initiate transactions or to respond to initiations. However, each actor in the network has the opportunity for transactions with at least one other actor in the network (Emerson, 1972).

Since an exchange network represents the sum total of exchange opportunities for an actor, and since those opportunities are dependent upon the actor's location or position in the network, we can consider the exchange network as analogous to that aspect of social structure which is of most concern to us (i.e., the opportunity structure for obtaining desired goods). We therefore shall use exchange network and social structure interchangeably.

Given the on-going nature of exchange relations, actors are not likely to base their decisions entirely on the benefits to be obtained from immediate transactions but also will consider the payoffs and costs resulting from transactions over time. It is probable, therefore, that actors, preferring to keep resources in reserve for future transactions, will not spend all of their resources in any single transaction. Moreover, since they cannot attain desired goals in isolation but are dependent on each other's resources, actors will have to consider mutual contingencies in contemplating transactions. Thus, it is unlikely that parties to a transaction will be able to maximize benefits and minimize costs in any absolute sense (see Buckley et al., 1974, for a detailed discussion of this point). Nevertheless, since desired goods are scarce, actors should be in competition for such goods.

It would seem that actors are on the horns of a dilemma. How can the various parties obtain what they want given mutual dependence, competitive goals, and a need to withhold resources? Clearly, all parties in the transaction cannot maximize their payoffs. If a transaction is to be completed, therefore, some coming to terms with what each party wants is necessary. This, we suggest, is accomplished through the process of bargaining.⁴ Research on bargaining indicates that through this process actors move from idealized to realistic probability estimates of what can be obtained in given exchange relations (see Patchen, 1970).

There is also evidence suggesting that actors enter into bargaining with preconceptions of the limits or range of exchange rates that they will consider acceptable (Komarita and Chertkoff, 1973; Ofshe and Ofshe, 1970a). That is, if the exchange rate demanded is too high or too low they will not complete the transaction. Such exchange rates are the product of transactions conducted over some time. They reflect both the value placed on specific goods by the social network and the agreed upon standards of fairness or justice adhered to by members of the network. In the following sections we shall seek to identify the specific structural variables which influence the formation of values and standards of distributive justice.

A. Social Structure and Value Formation

We shall restrict our use of the term *value* to mean a preferential ordering that is relatively stable over time. The qualification that preferences are stable is congruent with conventional meanings of the term *value* (Heath, 1976; Rokeach, 1973:248-71). Our conception of value thus excludes momentary fluctuations of preference reflecting physical or psycho-

⁴ The relevant literature and research related to this assumption includes not only the so-called rational theories of bargaining and negotiation (e.g., Bartos, 1972), but also work related to identity negotiation (Gergen and Taylor, 1969; Goffman, 1963; 1970; Weinstein and Deutschberger, 1963) and other forms of interpersonal exchange (Gergen, 1969; Jones et al., 1965).

logical reactions to deprivations and satiation. Our effort to explain the basis for actors' valuing some goods over others will be facilitated if we can generalize to types of goods. To this end, we adopt Emerson's (1972) concept of *Exchange Domain*. An exchange domain will signify that subset of goods which are viewed by actors as equally capable of satisfying specific needs; thus, each good within the domain is substitutable for the other.

We draw upon the economic principle of marginal utility to explain the basis upon which exchange domains are valued. Our use of marginal utility, however, depends upon human perceptions pertaining to the supply of goods rather than upon assumptions as to the actual supply. This reliance on perceptions allows us to avoid the unrealistic assumption that perfect knowledge exists about the available supply of goods. With this qualification in mind, we propose that the value of a domain varies directly with the perceived utility to an actor of the domain's goods. Utility is determined by the good's satisfying potential; and satisfying potential, in turn, is determined by: (1) the good's potential to please or satiate an actor if it is consumed or possessed, and (2) the good's availability to the actor. Since the domains we shall be concerned with have equally high need satisfaction potential, the consideration of point (1) above will not be relevant for our purposes. Thus, we conclude that the more scarce an actor perceives a domain to be, the more highly the domain will be valued. Applying the principle of diminishing utility, we propose that the more highly an actor values a domain, the more s/he will be willing to spend of his/her resources for additional units of the domain's goods up to some optimal point after which the actor's valuation of the domain declines and s/he will be willing to spend less for subsequent units. It is important to note, however, that the utility of a domain for an actor is not limited only to the satisfaction it provides through consumption or possession. If a domain is perceived as scarce by members of an exchange network it may be highly valued by actors even if they control large quantities of the domain's goods. This is because the actor who con-

trols large quantities of a scarce good is in a strong bargaining position. That is, s/he is in a position to demand more in goods and services from other actors in the network in exchange for units of the valued domain's goods than would be the case if such goods were plentiful or equally distributed. We shall discuss the reasons for this bargaining advantage below; our point here is simply that being in a strong bargaining position is a valued circumstance, and, therefore, a domain may be valued not only because of its scarcity to an actor, but also because of its perceived scarcity within the social structure.

Whereas scarcity/abundance is hypothesized as the key structural variable affecting the value placed on a domain by members of the social structure, the distribution of the domain's goods among the members of the structure is hypothesized as the key variable influencing the formation of norms of distributive justice.

B. Social Structure and Norm Formation

A reasonably safe generalization about observable social structures is that they are characterized by an unequal distribution of valued goods. As we previously noted, those who control greater amounts of the good are in a stronger bargaining position than those who control lesser amounts (Heath, 1976:24; Cook and Emerson, 1978). This is because the former have two advantages: first, they can withhold their resources longer than persons in weaker positions, and wait until they are satisfied with the rates of exchange; and, second, they have a competitive advantage for acquiring additional units of the desired goods (i.e., they are in a position to offer more of their resources for additional units of the desired good) than weaker competitors. However, since all members of a network are to some degree mutually dependent, some form of cooperation between at least a subset of the exchange network is necessary or no transactions will occur. This need for cooperation in an essentially competitive situation leads to the formation of coalitions. By forming a coalition, actors can pool their resources, thereby increasing the strength of their collective bargaining

position vis-à-vis other members of the social structure.

There is considerable support from coalition research with small ad hoc groups for the proposition that actors will seek to form coalitions with those others whom they believe can best facilitate improving their payoffs (Ofshe and Ofshe, 1970a; 1970b; Komarita and Chertkoff, 1973). It is important to note, however, that for the individual actor, payoffs are not only determined by forming a winning coalition but by the *share* or split each member of the coalition receives when a transaction is successfully completed. The decision as to how the reward is to be divided, as Komarita and Chertkoff (1973) demonstrate, may be determined by the bargaining process. They suggest that in bargaining situations actors implicitly or explicitly will estimate the most favorable outcome they can expect, the least favorable outcome, and the most probable outcome. These represent the parameters within which bargaining takes place; parameters which can be interpreted as distribution rules. Komarita and Chertkoff report that the distribution rules advocated by actors differ depending upon their bargaining strength. Thus, actors in weak positions (controlling few desired resources) advocate splitting the payoff equally among members of the coalition; and those in strong positions (controlling large amounts of desired resources) advocate splitting the payoff proportionately to the original resources held by members of the coalition. This finding is in accord with Robinson and Bell's (1978) *underdog principle* which holds that "... individuals who objectively benefit from the stratification system ... are more likely to judge its inequalities to be just," whereas, "... people who are objectively less well off are more likely to judge equality to be fair." Robinson and Bell present data from samples in England and the United States which generally support this principle.

The underdog principle, however, requires some qualification. There are data which suggest that economic conditions alone do not provide a sufficient explanation for people's adherence to equalitarian distribution norms (see Robinson and

Bell, 1978; Lane, 1959). Variations in such norms have been attributed to working conditions (Blauner, 1964), beliefs that are unique to specific cultures (Alford, 1963; Lipset, 1963; Robinson and Bell, 1978), and educational differences (Robinson and Bell, 1978). The recent work of Cook and Emerson (1978) offers the potential for subsuming these various findings under the stipulation that adherence to specific distribution norms depends not only upon one's resources, but also upon one's perception of available opportunities to form coalitions. They report that the norm of equity is activated when subjects are made aware of how resources have been distributed across the exchange network. They also found that actors who repeatedly engage in transactions with the same people constrain the use of their power advantage. Both of these findings indicate that opportunities to engage in transactions with other actors in the network affect the distribution rules which are applied.

Norms of Distributive Justice and Solidarity

An examination of all the possible combinations and complexities represented in extant social structures is beyond the scope of this paper. What we can do, however, is consider some key prototypes linked to aspects of social development.

Assume that in a given social network an actor (A) controls a large amount of resources desired by other actors in the network. These actors (B_1, B_2, \dots, B_n) are more numerous and all control small amounts of a good desired by A. B's are in competition with each other for their share of A's goods. This situation is analogous to the position of peasants raising the same crop in relation to a landowner or purchasing agent. It is also equivalent to unskilled, unorganized workers in a one-industry community. From the point of view of the actors involved this structure can be described as a two-class system. This type of a structure gives A a strong bargaining advantage. Given this monopolistic advantage A can offer any B a small inducement and feel virtually as-

sured that if B_1 does not accept, B_2 or B_n will. One solution for B's would be to form a coalition against A. Such a coalition would depend upon the structural opportunities provided B's to interact with each other. Peasants living in villages, for example, should have a greater opportunity to form coalitions than peasants living in isolated land tracts. Given such opportunities, the coalition formed by B's would be based on the distribution norm of equality. That is, the pay-off which would accrue because of the stronger bargaining position of the coalition would be split evenly between all B's.

The formation of such a coalition, however, is problematic and, therefore, unstable. The problem for individual B's is that A, faced with an opposing coalition of B's, is in a position to offer any particular B a larger pay-off than s/he would receive if s/he cooperated with other B's in the coalition. Thus, if B's are to maximize individual payoffs, we would anticipate that they should seek to form a coalition with A. But, such a coalition would be of benefit to B *only* if other B's continue to cooperate with each other and adhere to the norm of equality in their negotiations with A. If, on the other hand, all or most B's compete with each other to form an agreement with A, the situation reverts to the original monopolistic condition and B's would again lose bargaining power. Under such conditions, B's should seek to form a coalition with other B's. Thus, at this point, our theory is indeterminate. The problem is how can B's form a relatively stable coalition?

B's are in a dilemma analogous to the choices faced by players in the Prisoners' Dilemma Game. The long-run solution to this dilemma is cooperation among B's with acceptance of the lower risk but less remunerative norm of equality. However, because the temptation not to cooperate is high, the threat to the collective good is also high. This condition should generate distrust and suspiciousness among B's. One way to deal with such distrust is to increase the cost of members defecting from the coalition by making norms of cooperation stronger. Bonacich (1970; 1972; 1976) reports that norms stressing

cooperation, solidarity, and group cohesion, become more intense when the opportunities for individuals to maximize individual benefits at the cost of collective good are perceived as higher. Thus we would predict that given actor's perceptions of the two-class situation described above, a coalition of weak members is most likely to form if opportunities exist for interaction between weak members. We also would expect that such coalitions would advocate norms of equality. Conversely, given actor's perception of the two-class structure, norms of proportionality are more likely to occur if: (a) weak members in the structure do not have opportunities to communicate with each other; (b) weak members do not form norms of group solidarity or emphasize group cohesiveness; and (c) weak members believe they have a chance to form a coalition with strong members without incurring sanctions from other weak members.

Jerdee and Rosen (1974) present experimental evidence which reports that subjects were more likely to make "socially responsible" bids in a simulated business negotiation when they had the opportunity to communicate with each other. Bendix (1976), using an historical level of analysis, also provides support for this point. He suggests that European states in the eighteenth and nineteenth centuries prevented the lower classes from congregating because that would enable lower class people to advocate their own interests, a precondition for citizenship.

The two-class system we have depicted may be viewed as analogous to early stages of modernization or industrialization. Students of social development from Durkheim to the present tend to agree that with increasing industrialization, social structures become progressively more diverse. (See Marsh's [1967] review of the relevant literature.) We need not take the space to develop the relationship between structural diversity and an increasingly complex division of labor since most sociologists are familiar with the argument and the data. (See, for example, Durkheim [1949]; Horowitz [1966:431-53]; Smelser [1966].) Our special concern here is with

the effect of such diversity on norms of distributive justice.

Let us, for simplicity's sake, introduce a third class, C's, which offers a unique set of goods and services to members of the social structure. We assume that C's have accumulated sufficient resources to have bargaining power somewhere between A's and B's. With the introduction of this third class the coalition between B's is weakened because the structure is also dependent on C's, thereby requiring that all negotiations and coalitions include not only A's and B's but also C's. Since three levels of bargaining strength are represented, the norm of equality which derives from coalitions among members in the weakest bargaining position is less likely to predominate. Both A's and C's should seek payoffs proportionate with their greater resources. We would predict, therefore, that the greater the complexity in the division of labor within a social structure, the more likely the prevailing norms of distributive justice for relevant exchange domains will be based on the principle of proportionality. Further, given the proposed relationship between norms of equality and norms of solidarity, we predict that the greater the complexity of the division of labor within a social structure, the less likely the norms of group or class solidarity or cohesion will be stressed.

APPLICATION OF THE THEORY TO MEXICO AND THE UNITED STATES

Of the various macroindicators of social change and development reported in the literature, the three most prevalent, and, in our view, most germane, are income distribution, rates of industrialization, and patterns of social relationships. At the microlevel, these indicators involve decisions in two primary exchange domains. One pertains to material rewards such as money, jobs, investments, etc. The other domain relates to rewards associated with interpersonal relationships, such as affection, feelings of closeness, respect, and so forth.

A central question affecting the course of social change is the relative emphasis members of different societies place on

achieving rewards in each of these domains. Although we can reasonably assume that most people would like to maximize rewards in both domains, sociologists from Tönnies to Parsons have argued that maximizing one tends to be at the cost of the other (see also Lee, 1977:257-96 for relevant empirical evidence). We would hypothesize, therefore, that persons living in social structures characterized by a scarcity of material goods will place a greater value on material well-being than on interpersonal relations; conversely, social structures characterized by material abundance will place a higher value on interpersonal relations. We also predict that if structures differ in the abundance of material goods, the differences in the valuation of such goods will be greater between structures than within structures. Thus, differences in values placed on consummatory goods should be less pronounced between classes within a society than between societies, if those societies represent different levels of development. Finally, we predict that the people living in developing or modernizing structures will spend more of their resources to obtain material goods, whereas those residing in industrialized structures will make greater expenditures in obtaining interpersonal rewards.

Regarding norms of distributive justice, we predict that persons in highly developed social structures are more likely to advocate the norms of proportionality in the distribution of goods within a social structure, whereas members of social structures with less complex divisions of labor are more likely to advocate norms of equality. Moreover, the norms of group solidarity and norms of equality should be more evident among persons residing in social structures which are perceived by their members as containing relatively few social classes.

If these predictions hold, we can conclude that with societal development, norms of distributive justice change from an emphasis on equality to one of proportionality and from an emphasis on group solidarity and collective well-being to a more competitive and automatized orientation. Such conclusions are in accord with

descriptions of Töennies, Nisbet, and others. What we are suggesting is that these norms can be derived from the assumption that responses to structural conditions are motivated by self-interest.

The data we shall use in testing the utility of this theory were gathered in a cross-national study conducted in Mexico and the United States. The primary focus of the research was on the relationship between social structure, family socialization practices, and children's problem solving. Although the underlying model used in the study derived from exchange theory, many of the specific elements of the theory presented here were developed after the data were gathered. The findings, therefore, do not represent exact tests of hypotheses. On the other hand, they do not represent postdatum interpretations. We have not altered our original hypotheses since the data were collected; we have, however, refined our explanations (see Tallman, 1972).

When we gathered our data, Mexico was described as one of the two or three most rapidly developing countries in the world (AID, 1973). Nevertheless, its per capita income, the large discrepancy in income among its population, and its level of industrialization and productivity placed it among the modernizing as opposed to the industrialized countries of the world. The United States, on the other hand, especially in 1972 when the data were collected, was considered one of the most affluent nations in human history. Although the rate of increase in productivity was not as great as among other countries, it, nonetheless, epitomized a supreme industrial state.

The samples drawn for this study came from four peasant villages in the state of Michoacan, Mexico, Zacapu, an industrial town in the same state, and the Twin Cities in the state of Minnesota in the United States. Although the state of Michoacan is not among the most prosperous or highly developed in Mexico, the town of Zacapu had had considerable economic and demographic growth. In a 30-year period it had changed from a traditional market town of about 6,000 to an industrial urban center of 35,000. In many ways, Zacapu was more typical of Mexi-

can development than the large metropolitan centers. The Twin Cities represented a reasonably typical affluent United States metropolitan area. In sum, we compared residents of communities which, though characterized by economic scarcity, were undergoing rapid economic development, with residents of an affluent community which was experiencing a limited rate of growth.

The area in Mexico from which we drew our sample has been the subject of numerous ethnographic and descriptive studies (Foster, 1948; 1967; Beals, 1946; Nelson, 1971; Friedrich, 1970; and Pi-Sunyer, 1973). Although the two-class system we depicted is a simplification of the village social structure, we believe it closely approximates the structure of the villages we studied. Ethnographers usually report three graduation levels within what we would consider a poor class; despite these gradations the primary occupational roles are poor farmers and landless laborers, both of whom are dependent upon those who control larger fiscal resources, usually wealthy merchants, factory employers, or governmental officials all operating outside the confines of the particular villages (see, for example, Nelson, 1971:27-32, 46-53; and Pi-Sunyer, 1973:100). The villagers represented a lagging part of the changing Mexican economy; their lives had changed less than other socioeconomic groups in Mexico (Pi-Sunyer, 1973:99-100). Nevertheless, they were part of a money rather than subsistence economy, and like villagers elsewhere in Mexico, they were aware of changing opportunities, especially for their children (Miller, 1973:127; Diaz and Potter, 1967).

There is evidence, however, that peasants perceive of themselves as a single class in their struggle to attain material goods. The peasants in Michoacan have been characterized, as have peasants elsewhere, as being highly distrustful and suspicious of one another (Foster, 1967; Rogers, 1969). At the same time, a number of observers have noted the "leveling norm" which permeates peasant existence. Foster (1967:123-5) relates this to an "image of limited good" which assumes that all valued goods exist in such limited

quantities that "... an individual or family can improve its position only at the expense of others." Nash (1967:538) claims of peasant village life that "no one can run the risk of wide economic differentials."

These two phenomena, suspiciousness and an emphasis on the leveling norm (i.e., equality), are, as noted earlier, predictable from the two-class structure described above. We, therefore, would expect that peasants, in addition to advocating the norms of equality, would also advocate norms of solidarity. That is, it is precisely because of vulnerability and suspiciousness that the norm of solidarity is enforced.

Nash, among others, has argued that the leveling norm inhibits individual incentive and retards the peasants' potential for risk-taking and innovation. Interestingly, virtually the same conclusions are made by those who interpret the peasant life as family oriented. Rogers (1969) claims that peasant life is primarily familistic and only secondarily individualistic. Rewards reaped through individual effort must be shared by the other members of the family, so it is familistic orientations which explain the peasant's relatively low level of aspiration. It would appear that these chroniclers of peasant life believe that only a normative system which stresses the individual as the proper beneficiary for rewards can produce people willing to take advantage of opportunities for economic advancement. Such a conclusion not only runs contrary to our predictions, but, from the perspective of our theory, poses the problem in the wrong terms. Given our assumptions, the key issue becomes not whether the individual is viewed as a proper beneficiary of rewards, but what rewards the individual values most highly and would be willing to sacrifice to attain. Based on the prevailing conditions in Mexico we predicted that Michoacanos would put material advancement above interpersonal considerations including loyalty to family; we predicted the inverse relationship for the Twin Cities sample. The reported commitment peasants make to familism can be interpreted as a recognition of their economic interdependence with kin rather

than a concern for interpersonal satisfactions (see Miller, 1973:136-7, 139; Firth, 1969; Lomnitz, 1977). If this is true, then peasants should be ready to abrogate family commitments if they no longer are economically advantageous. The study we shall discuss below provides a test of this contingency.

Research on the values of Mexican city dwellers is sparse and it is difficult to discern general themes. Miller (1973) and Pi-Sunyer (1973) both emphasize that although the social structures of towns and cities contain a middle class and some upper-class elements, the vast majority are poor people of peasant origin. Pi-Sunyer (1973:33-4) concluded in his description of the Michoacan town of Zamora that "the povres of Zamora . . . have much more in common with the campesinos (peasants) of the little Mastizo ranchos (hamlets) than with the bourgeoisie of the town." Research evidence pertaining to white-collar persons is even more sparse. What little evidence there is, however, suggests that these groups are highly motivated to attain both social and material advancement (Miller, 1973:126-7).

With regard to the United States, in 1972 there was some research to support the hypothesis that there is a shift away from material attainment toward interpersonal well-being and concerns. Studies by Litwak (1959) and Sussman and Burchinal (1962) have shown a considerable emphasis on families' "helping" behavior and a disavowal of the notion that young people are on their own once they leave the "nest." Bell (1958), Mowrer (1958), and Riesman (1957) have all documented a tendency on the part of middle-class whites to move to the suburbs primarily to provide better living conditions for their families and to avoid the "rat race." Sennett (1970) argued that growing familism in the United States was at the cost of both individualism and a commitment to community.

The growth of suburbia, combined with increased affluence and a high emphasis on consumption, had contributed to an increasing tendency to disavow both material attainment and the commitment to upward mobility (Flacks, 1971). Gottlieb

(1973) reported an inclination among college students to emphasize job satisfaction over job status. Increasing attention was given to the notion that postindustrial America, especially the middle class, was relinquishing its commitment to work and upward social mobility. Berger and Berger (1971), for example, suggested that because of this new orientation, more high-level positions would be filled by children from blue-collar families than was true of earlier generations.

Despite the popularity of this view of a new America, it tended to be supported by arguments and description rather than data. When data were presented, they were drawn primarily from political activist groups which were not necessarily representative of the larger society. The question of whether a fundamental non-materialistic shift had occurred remained open.

Hypotheses

The following hypotheses derived from our theoretical perspective pertain specifically to the samples we studied.

Hypothesis 1. The Michoacan samples will place higher values on life goals stressing material attainment than on life goals stressing interpersonal commitments such as familism; whereas, the Minneapolis samples will evidence higher values on life goals involving interpersonal satisfactions such as familism, than on material attainment.

Hypothesis 2. The Michoacan sample will indicate a greater expenditure of personal resources (time, money, energy) in attaining material goals; whereas, the Twin Cities samples will spend greater resources in attaining interpersonal rewards.

Hypothesis 3. Differences in values on material advancement and interpersonal relationships should be less pronounced between social classes within a society than between societies.

Our predictions pertaining to norms of distributive justice are based on the inference that the social structure of peasants and workers in Mexico fosters their perception of social structure as made up of two social classes; whereas the complex-

ity of the United States social structure fosters the perception of multiple social classes.

Hypothesis 4. Michoacan peasants will be the most likely group to advocate norms of equality in distributing material goods followed in descending order by Michoacan blue-collar workers, Michoacan white-collar workers, Twin Cities blue-collar workers, and Twin Cities white-collar workers.

Hypothesis 5. Adherence to the norms of proportionality in distributing material goods will follow the reverse order from that predicted in Hypothesis 4.

Hypothesis 6. The peasant and Mexican blue-collar samples will place a greater value on community solidarity than on individual or family well-being; whereas, the blue- and white-collar United States samples will place a greater value on family well-being. The Mexican white-collar sample should fall in between these groups.

METHOD

The research reported here is part of a larger comparative study on socialization for social change. For this study, independent interviews were conducted with mothers and fathers of 12 to 15-year-old boys and girls in four rural villages and the city of Zacapu in the state of Michoacan, Mexico, and in Minneapolis/St. Paul, Minnesota. A proportion of the interview sample was then selected to participate in a game simulation in which families consisting of a mother and father and a 12 to 15-year-old son or daughter planned the career of the child. The game-simulation was conducted in two phases, one in which the family played the game as a unit and one in which the child played the game alone, under conditions of simulated social change.

The Zacapu blue- and white-collar samples were randomly drawn from school lists of children in the appropriate age brackets. As such they did not reflect the poorest or marginal segment of the population which may have withdrawn their children from school prior to the age of 12 (Lomnitz, 1977). The village samples represented virtually the entire population of

children in the appropriate age brackets. Because of the greater cultural and ethnic homogeneity of Mexico as compared with the United States, the Twin Cities sample was drawn largely but not entirely from Lutheran and Catholic families selected from church membership lists. The churches were selected by using census data to maximize representativeness within each of the religious groups. A smaller subset of the sample was drawn from neighborhood listings in blue- and white-collar suburbs surrounding Minneapolis. The total number of families sampled was 112 in the villages, 160 in Zacapu, and 149 in the Twin Cities. Of this group, 50 village families and 82 families from both Zacapu and Minneapolis/St. Paul were selected to participate in the game simulation.⁵

The interview schedule was first written in English and translated into Spanish. It then was pretested in both countries. Back translations were made for only those items which proved troublesome for the Mexican and United States collaborators. The original schedule was developed in close collaboration with our Mexican colleagues at the Instituto Mexicano de Estudios Sociales. The Mexican interviews and the original coding of responses were done by native speakers.

The game simulation, to which we attached the acronym SIMCAR (Simulating

Career Choice Patterns), was constructed in keeping with an economic-consumption model. The way to do well in the game was to choose alternatives which emphasized attaining high-status jobs and financial return. This required deferred gratification and advanced planning. In the game participants made decisions concerning the investment of time and money in each of 17 choice areas beginning with the child at age 16 and ending at age 27. The game simulated occupational, educational, marital, religious, and consumption decisions typically made by and for youth in late adolescence and early adulthood (see Tallman et al., 1974; and Tallman and Wilson, 1974, for a detailed description of the game simulation).

RESULTS

Table 1 presents the findings relevant to the first three hypotheses. This Table summarizes both the final payoffs and the investments (time and money) made by the children in the various samples while playing SIMCAR.⁶ Since investments for

⁶ The data from the family game are not appropriate for this analysis because families played the game under different treatment conditions which affected the family performance. The purposes of these manipulations were to test hypotheses pertaining to family experiences of success and failure on children's performance. These manipulations do not systematically affect the results reported in Table 1, however, since families were randomly assigned to treatment cells within the categories of class and community and the treatments were counterbalanced.

⁵ The final N's for families participating in the simulation game differed because of errors in cell assignments and errors during the game which required additional sampling.

certain rewards in the game required forsaking other rewards, the payoffs reflected in Table 1 indicate the actors' preferential ordering of the choices available. Hypothesis 1 predicted that Michoacanos would adhere to values which enhanced material attainment and Twin Cityites would adhere to values which emphasized better interpersonal relationships. An overview of Table 1 indicates that the data support the hypothesis. The data also support Hypothesis 2. The Michoacan children were significantly more likely to obtain higher job ranks, earn more money during the game, and spend more money in the store. Conversely, the Twin Cities children invested significantly more time and money in friends and dates, were significantly more likely to get married, and chose to have more children. Finally in support of Hypothesis 3, the differences were greater between societies than within societies. Controls for parent's income, education, religion, and family size applied within societies studied did not seriously attenuate the findings.

Only the findings pertaining to relatives were not in accord with the hypotheses. Here class differences as well as differences among the three communities were evident. The village children and blue-collar children in both Michoacan and the Twin Cities were significantly more likely to visit relatives than white-collar children in either society.

These data suggest that the Michoacan children in our study not only were more likely than Twin Cities children to seek material gain, but also were aware of and willing to commit themselves to life styles which would maximize these gains. Attaining the highest job ranks, for example, required commitments to education and job experience in the early rounds of the game. Obtaining sufficient income to make store purchases required delaying having children and saving money. The Twin Cities children in our sample demonstrated a greater commitment to maximizing social and family relationships, even at the cost of obtaining higher job ranks and greater income.

Hypothesis 4 predicted that the norms of equality in exchanges pertaining to

material goods would be most highly emphasized by Michoacan peasants followed by Michoacan blue-collar workers, Michoacan white-collar, Twin Cities blue-collar, and, finally, Twin Cities white-collar workers. The reverse order is hypothesized for advocacy of the norms of proportionality (Hypothesis 5). Our data did not allow us a direct test of these hypotheses. Respondents were not provided an opportunity to decide how to divide or distribute a reward. We did have questions in the interview, however, pertaining to whether respondents would want to equalize an unequal situation or whether they believed that people or groups with greater resources should be more highly rewarded. The former type of response represents an equality norm and the latter type of response we interpret as representing a proportionality norm. To test the hypotheses we used three items from an index developed to assess concepts of distributive justice. The items posed alternative statuses and/or investments affecting particular situations and asked respondents to choose which of the alternatives should be rewarded. One of the questions posed alternatives which required either equality or proportionality answers. The question was as follows:

Two rural communities apply for government funds to improve farm production. One community has shown it can do very well on limited resources and has a higher level of productivity than the other community, which is extremely poor. Which community should get the funds?

Choosing the poorer community was coded as an equality response and choosing the productive community was coded as a proportionality response. The second item posed the norm of equality against assisting kin. It stated:

Imagine you own a farm and you want to hire one person to help you. Two people who are equally good workers apply. One is a relative who is not very poor. The other is a stranger who is very poor. To whom would you give the job?

Those who stated "stranger" were coded as making an equality response. The third item pitted age and/or need against proportionality. It posed the following situation:

An uncle wants one of two sons in a family to go to work for him. It is a job which pays well and both boys want to go. The younger boy has had experience in this kind of work. The older boy has no experience and has not shown an interest in this type of work before, but needs the money badly. Who should go?

Those who respond in favor of the younger child were coded as giving a proportionality response.

The findings presented in Table 2 generally support Hypotheses 4 and 5, although the findings are stronger for the male respondents than for female. The villagers and Michoacan blue-collar workers were more likely to advocate norms of equality and least likely to advocate proportional norms. The Michoacan white-collar respondents were lowest on equality and highest on proportionality.

The data with regard to blue- and white-collar Twin City males and females are less clear-cut. Although both groups are more likely to advocate proportional norms as predicted, the blue-collar males were also significantly more likely than white-collar males to advocate equality on the second item ($\chi^2 = 9.72, p < .01$). In fact, on this item the Twin Cities blue-collar males ranked second only to the villagers in percent choosing the equality item. This was also the only item in which no significant differences occurred among the women sampled. Any interpretation of this anomaly in our findings would be entirely speculative.

Data pertaining to the final hypothesis is presented in Table 3. Hypothesis 6 predicted the same ordering for advocating the norm of collective solidarity as Hypothesis 4 predicted for the norm of equality. To test this hypothesis, we used four questions from the interview schedule. Each question was in the form of three statements asking whether the community, the individual, or the family should be the recipient of a given benefit. Each of the questions focused on a different reward. The first question, for example, was concerned with social control and asked whether it was preferable to have a safe community, to teach children to behave, or to control oneself. The second question referred to interpersonal relations and

stressed getting along with neighbors, family, or feeling good about oneself. The third group of statements referred to who should be the proper beneficiary of earned income. Unfortunately, in this set the self and family choices were confounded. In an effort to distinguish between nuclear and extended family, the self statement read, "Making a lot of money for myself and my family," whereas the family statement read, "Making sure my parents are well cared for." The final set of statements pertain to the proper recipient of happiness.

It can be seen from the bottom three rows in Table 3 that, when all four items are summed, Michoacanos tended to stress community welfare significantly more frequently than Twin Cityites. Conversely, Twin Cityites were significantly more likely to emphasize family well-being. This latter finding probably would have been even more pronounced if it were not for the confounding of the question referring to money. As predicted in Hypothesis 6, the villagers in Michoacan placed the greatest emphasis on community and the white-collar urbanites placed the least emphasis on this category. Again, these differences were more pronounced for men than for women. A similar differential did not occur between white- and blue-collar men in the Twin Cities. One possible explanation for the lack of differentiation in the United States as compared with Mexico is the larger discrepancy in income and life styles between each of the social classes in Mexico.

An examination of the separate questions reveals that the emphasis on community is most pronounced on the income question for villagers and on the interpersonal relations question for Michoacan urbanites. The happiness questions provide indirect support for the proposition that the norm emphasizing community benefits is designed to maximize individual rewards. It can be seen that this is the only item in which the vast majority of Michoacanos stressed personal gain, whereas around 90% of the Twin Cityites emphasized family happiness. One interpretation of this finding is that the Mexican emphasis on community in the other

Table 2. Respondents' Choice of Appropriate Beneficiary on Three Distributive Justice Items by Husbands and Wives, Class and Community* (Percentages)

items can be viewed as fostering their individual well-being, whereas the North Americans consistently emphasize the importance of interpersonal contentment.

SUMMARY

The data presented with regard to norms of distributive justice are in accord with ethnographic reports describing Mexican peasants and, less frequently, blue-collar Mexican urbanites. The commitment to community welfare and the leveling norm has received wide circulation in the literature describing Mexican life. What we suggest here, however, is that contrary to common interpretations these norms do not impair their adherents from seeking material advancement. Rather, given the scarcity of material goods and broad differentials in the distribution of these goods, such norms can be viewed as rational commitments to attaining the best return possible under prevailing conditions.

The fact that such norms do not deter people from seeking material gain is evidenced by the data on performance in the game simulation. The greater income and higher job ranks obtained by participants could only come about by commitments of time and money to education, study and savings. The game simulation behaviors are not, of course, illustrative of how people actually live their lives but they are suggestive of how people would like to live if they had the opportunity.

Our data provide support for Apter's (1971) hypothesis that people in countries in advanced stages of modernization tend toward embourgeoisment. This is demonstrated by findings pertaining to job ranks and store purchases. A reasonable interpretation of these findings is that whereas the village children sought primarily to make as much money as they could, the Michoacan urban children sought high-status jobs and the opportunity to spend the money they earned on consumption items.

On the other hand, the data from the Twin Cities samples are in accord with perspectives describing the United States as a postindustrial society. The findings with regard to both distributive justice

norms and performance in the game simulation indicate major concern for fostering interpersonal relations and less concern for material equality or maximizing material gains.

Our data are limited in that the research is cross-sectional. We cannot, therefore, conclude that the differences we report are due mainly to differences in the level of development of the two countries. Nevertheless, the fact that the Michoacan children performed in a manner which almost caricatures the "Protestant ethic" descriptions of an industrializing America, whereas Twin Cities children seemed to be eschewing materialistic values, provides at least indirect support for the thesis that these behaviors are associated with postindustrial and modernizing levels of development.

CONCLUSION

We believe the critics of the exchange perspective have pointed correctly to the failure of the perspective to contribute adequate explanations of how collectivities develop and change mechanisms of social control. These critics, however, do not provide an adequate alternative explanation or pinpoint essential flaws in the exchange argument. For those committed to the Durkheimian tradition, developing linkages between individual and collective behaviors are by definition inappropriate and unnecessary. "... Social institutions, norms, and values grow out of the moral mandates of society" (Ekeh, 1974:185). Therefore, "... social exchange is a supraindividual process and individual self-interests may be involved in it, but they cannot sustain social exchange processes" (Ekeh, 1974:43). To accept this perspective is to eliminate the potential for analyzing the decision and behavioral processes through which people agree or disagree, adhere or reject, conform or deviate from a variety of mechanisms of social control. It is true that individuals involved in these processes operate under social constraints, but to ignore their contribution to the formation of norms and other methods of social control is to obfuscate the mechanisms

through which commitments to the collectivity are established and altered.

There is another body of criticism of the exchange perspective which, though it seriously considers the impact of individuals on collective action, argues that rational self-interest and collective well-being are antithetical. This approach, exemplified by the work of Buckley et al. (1974) makes an important distinction between individual decision making and collective decision making, and suggests that the exchange framework does not contribute to our understanding of the latter. Buckley et al. point out, correctly we believe, that individuals' behaviors are constrained by a number of social contextual factors, including access to material or social resources and the inability to control the actions of others. Thus, actors must consider their own resources compared with others' resources and their own preferences compared with others. They conclude:

Both game theory and the economic model of exchange and its derivative in sociology, exchange theory, ignore the possibility that human beings may be unable to or, in many instances, unwilling to calculate immediate rewards and costs in social transactions. . . . [S]uch theories fail to consider that exchanges may be initiated in order to establish or maintain a relationship, e.g., bonds of trust or friendship or superordination over others. . . . (Buckley et al., 1974:294)

In brief, Buckley and his colleagues provide four basic premises related to collective decision making:

1. Individual decisions are embedded in a social context.
2. Individuals must take into account mutual contingencies in which their own resources are considered in relation to the resources of others and their own preferences considered against the preferences of others.
3. Social actors must consider the transactions between people in terms of long-range as well as immediate payoffs.
4. Individuals value exchange domains other than those involving goods and services.

We consider these premises to be essential for an adequate explanation of collective decision making. They do not, how-

ever, necessarily contraindicate principles integral to the exchange perspective. In the theory and data presented in this paper, we have attempted to show how the above premises can be integrated with exchange principles (including the individualistic and utilitarian assumptions), to explain the formation of specific social norms and values.

Our theory is limited to specific values and norms of distributive justice. It is related to evolutionary—not revolutionary—social change. It pertains specifically to differences between modernizing and industrialized states rather than to the entire range of social development. Yet there are implications for a broader theory of development. It seems reasonable to consider that perception of society as a two-class structure is most conducive to mass revolution primarily because it is associated with intraclass solidarity and norms of equality. This may be one reason why Marx, despite a sophisticated sensitivity to conflicting interest groups in nineteenth century Europe, insisted that at the core, capitalism is a two-class social system. And Lenin, in his prerevolutionary writings, advocated policies which would reinforce the concept of two opposing classes in Russia, even at the cost of resolving current social ills.

At the very least the theory and the data we have reported raise serious questions as to the claim that traditional beliefs and norms tend to impede the course of economic development. A more reasonable interpretation is that people's choices are generally rational and amenable to change, given available information and opportunities. From this perspective three critical types of data seem necessary to explain the course of social development: 1. the degree of scarcity and distribution of material goods; 2. the type and nature of relevant information available for people to process; 3. objective estimates of the choices available in the social structure.

If the theory has merit, those with applied interests in institution building and fostering development well may focus less attention on creating opinion or normative change and more attention on the proper

dissemination of information in forms which can be processed and implemented. From the perspective of individual adaptations of innovations the problem is not that such innovations run contrary to culturally determined norms, but that they may not be perceived as instrumental in achieving desired goals.

From the perspective of a theory of social change, our theory suggests that norms and values change with the marginal utility of available goods and as comparison levels and available alternatives change within the social structure. Such structural changes occur as people with differing resources make decisions designed to maximize rewards and minimize costs in regard to salient domains.

SEX AND AUTHORITY IN THE WORKPLACE: THE CAUSES OF SEXUAL INEQUALITY*

WENDY C. WOLF AND NEIL D. FLIGSTEIN

University of Arizona

American Sociological Review 1979, Vol. 44 (April):235-252

This paper contributes to our understanding of the causes of the restriction of women from positions of authority in the workplace. We ascertain the extent to which the sex gap in aspects of authority can be explained by the following three factors: (1) women's qualifications, (2) the behaviors and policies of employers, and (3) the attitudes and behaviors of women themselves. We find that while the amount of sex difference in aspects of authority that can be explained by women's qualifications is substantial, it is not the most important factor responsible for the restriction of women from positions of authority. Furthermore, strong evidence is presented that suggests that the behaviors and policies of employers are much more important causes of sexual differences in authority in the workplace than are the attitudes and behaviors of the women themselves.

An individual's power and social position flows predominantly from his/her position in an economic organization, be it large or small, public or private (Dahren-

dorf, 1957; Galbraith, 1969). The essential feature of power in organizations is the ability to control resources: capital, people's work, and things. Indeed, for most people, being "higher up" means precisely this: the ability to control one's work and the work process of others.

While men have obtained power through their positions in the work setting, women's power traditionally has derived from their roles in the family. It has been argued that women gained social position from the men in their lives, first from their fathers and then from their husbands (Parsons, 1942; 1955). This stems from the fact that until quite recently, women's traditional role obligations centered on marriage and childbearing, and their commitment to paid employment was viewed as secondary to their other role obligations (Myrdal and Klein, 1956; Parsons, 1942; 1955; Smuts, 1971). We argue that since,

We gratefully acknowledge the helpful comments of Bill Bielby, Dudley Duncan, Chuck Halaby, Mike Hout, Randy Hodson, Bill Sewell, Mette Sørensen, and the anonymous reviewers, as well as the computational assistance of Nancy Bode and Harold Varnis. Of course, any remaining faults are our own. We are grateful to Bill Sewell and Bob Hauser for making their data available to us. The authors and this research were supported by a grant to Bill Sewell and Bob Hauser entitled "Social and Psychological Factors in Status Attainment" from the National Institute of Mental Health (MH-06275-16), NRSA training grant HD07014, and a Center for Population Research grant (HD05876) to the Center for Demography and Ecology at the University of Wisconsin from the Center for Population Research of the National Institute of Child Health and Human Development.

in the past, women largely derived their social positions from their families, they were restricted from positions of power in the work setting. However, the traditional view of women's roles has begun to break down as more women are in paid employment and women are more likely to work throughout their lives. This results in women's employment becoming an integral part of the family's social position (Sampson and Rossi, 1975). Furthermore, more women are likely to head their own families (Ross and Sawhill, 1975) and rely on their own work activities to obtain power and money. In short, women's situations have changed, and many now rely on their own work activities as an important mechanism for obtaining power in society.

Despite these changes, women are much less likely to be in positions of power in the workplace than are men (Wolf and Fligstein, 1979; Grimm and Stern, 1974; U.S. Bureau of the Census, 1973). Furthermore, sexual differences in power in the work setting recently have been found to be an important factor generating inequality in earnings between men and women (Roos, 1978; Robinson and Kelly, 1977). If one is interested in remedying sexual inequality in the workplace, it is helpful to understand how these differences in power are generated. It is the purpose of this paper to contribute to the understanding of the allocation of men and women into positions of power in the work setting. We are concerned with legitimated power in the work setting: authority (Hall, 1972; Mechanic, 1962; Weber, 1947). We define authority as legitimated control over the work process of others.

What do we already know about sexual inequality in authority in the workplace? First, census data indicate that women are much less likely to be in the major occupation group, "managers and administrators, except farm," than are men.¹ Second, although women are highly rep-

resented in certain professional occupations (nurse, social worker, school teacher, librarian), men are overrepresented in the higher level positions within these professions (Grimm and Stern, 1974). Hence, even in the sectors of the labor force where women predominate, men tend to be in supervisory roles. In general, women tend to be excluded from occupations which by definition involve supervising others and they tend not to assume supervisory positions in work settings in which they dominate, let alone in mixed work groups. Recent research has shown that women are much less likely than men to be in positions of authority, even when they have the same level of education and occupational status, and that this difference cannot be explained by the fact that men are more likely to be self-employed (Wolf and Fligstein, 1979). In sum, there is evidence of marked sexual inequality in authority in the workplace.

No existing research suggests how these sex differences in authority in economic organizations are generated. We assess the relative importance of three sets of factors that partially account for the unequal distribution of men and women in positions of authority: (1) women's qualifications, (2) the behaviors and policies of employers, and (3) the attitudes and behaviors of the women themselves.

First, it is likely that women are restricted from positions of authority because they are less qualified on the following grounds: (1) their training, (2) their intermittent patterns of employment, (3) their lack of sufficient tenure and commitment to the firm, and (4) restrictions on their geographic mobility as well as travel for work purposes because of their family situations (Blau and Jusenius, 1976; Oppenheimer, 1970).

Second, the restriction of females from positions of authority may be due to the behaviors and policies of employers. Individual employers or persons with the power to hire and promote may restrict females from positions of authority because of their attitudes about women's ability to perform in supervisory positions. In this society, persistent sex-role

¹ Although most job titles that are in the major group, "managers and administrators, except farm," do involve control of others, a small number of titles do not. Some examples of this latter group are: railroad conductor, juror, bookmaker.

socialization has led to a well-defined division of labor within the family. This has had implications for the kinds of positions employers have thought were appropriate for women (Boulding, 1976; Bernard, 1976; Hartmann, 1976). Employers' views on women's ability to perform in positions of authority are shaped by employers' attitudes on what women's roles should be as well as the actual behavior of women. Many employers feel women are too emotional and are therefore unfit to be in supervisory positions (Kantor, 1977; Bowman et al., 1965). There is also a strong belief among employers and workers that women should not supervise male or mixed-work groups (Caplow, 1954; Kantor, 1977; Whyte, 1949; Oppenheimer, 1970; Bowman et al., 1965; National Manpower Council, 1957). In short, we argue: (1) that employers have strong feelings about the appropriateness and ability of women to assume supervisory positions, especially those positions involving supervision of mixed-sex or all-male work groups; and (2) that these attitudes affect the allocation of females into these positions. This is, in essence, a statistical discrimination argument (Phelps, 1972; Thurow, 1975) in that an individual female may be restricted from such a position regardless of her employment history because an individual employer believes that members of her sex, for whatever reason, are unsuited for assuming such roles.

Employers also restrict women from positions of authority because of rules and policies within the organization, but not necessarily specific to it. Segmented labor market theory suggests that women are placed in sectors where jobs have limited promotion possibilities (Doeringer and Piore, 1971; Gordon, 1972; Wolf and Rosenfeld, 1978). Because of these limited career progressions, women would be less likely to be in positions of authority than men. While labor market structures exist outside any given organization, they are reflected in the policies and practices of any organization. It is also possible that union/management contracts may inhibit women's movements into positions of authority. For example, contracts which specify "last hired/first fired" conditions

seem to have more impact on the career lines of women than men. In sum, we posit that employers' behaviors and policies have a marked impact on the sexual distribution of authority in the workplace.

Another reason for not expecting women to occupy positions of authority concerns some women's views of their own competence for such positions as well as their lack of desire to be in supervisory roles. Some women, not having been socialized into leadership roles, may see themselves as less capable of assuming such positions. Because women are more likely to anticipate interruptions in paid employment, they may be unwilling to make the long-term commitment to an employer that a position of authority often entails.

By empirically assessing the importance of these three factors for the explanation of the restriction of females from positions of authority, we will understand whether the major differences between men and women in authority are due to factors under the control of the individual or factors resulting from the behavior of others in the labor market. This is valuable as it suggests the direction that policy makers or people interested in achieving sexual equality in the workplace should direct their attention.

Analytic Strategy

In our empirical analyses, we will assess the importance of our various explanations of sex differences in authority in the workplace. This requires an approach that allows us to divide some measured difference into components that can be attributed to the various explanations we have suggested. To do this, we begin by estimating the following reduced-form equation separately for each sex:

$$A = f(\text{Ed}, \text{Exp}, \text{Ten}, \text{Cm}, \text{Chdn}), \quad (1)$$

where A is authority, Ed is education, Exp is work experience, Ten is tenure with current employer, Cm is currently married, and Chdn is whether the respondent had any children. Education, work experience, and tenure are tapping differ-

ent aspects of human capital. Marital status and the presence of children tap the restrictions on geographical mobility and travel for work purposes imposed on females by their family situations. The parameters in these equations indicate the differential effects by sex of an individual's qualifications on the acquisition of authority. Moreover, in estimating these parameters, we are able to determine the extent to which the gross sex difference in authority is due to women's inferior qualifications. We will decompose the gross sex difference in authority into three components: that due to composition on qualifications; that due to differential effects of these factors; and that due to the interaction between the two (Winsborough and Dickinson, 1971; Althausen and Wrigler, 1972; see Fligstein, 1976, or Halaby, forthcoming, for an example). The component due to differential composition of the sexes on these five factors represents the amount of the sex difference that is due to the fact that women have inferior qualifications (less labor force experience, education, or tenure with current employer or family situations which inhibit their assuming positions of authority). We use the reduced-form equations to derive such an estimate in order to obtain an upper bound estimate of the amount due to inferior qualifications. It is essential to identify the extent to which this explanation is operating as women presumably could increase their authority in the workplace by improving their qualifications. Here we are making the assumption that women are unable to improve, through their own actions, their returns on these characteristics. That portion of the sex difference in authority that is not attributable to composition on these characteristics is due to either of our other two explanations or other unspecified arguments.

In order to assess the importance of the behaviors and policies of employers and the attitudes and behaviors of women, we estimate the following equation separately for each sex.

$$A = f(\text{Ed, Exp, Ten, Cm, Chdn, Male, Unlabeled, Status}), \quad (2)$$

where Male is whether or not an individual is in a job that is predominantly male, Unlabeled is whether or not an individual is in a job that is not sex-typed, and Status is the occupational status of the job. These variables represent different characteristics of jobs.² There is an implicit ordering here. The human capital and family factors are attributes that an individual brings to the workplace, while the measures of job characteristics reflect aspects of the position an individual occupies in the work setting. Both sets of factors are expected to affect the probability of having authority in the work setting.

The parameters in these equations give us a mapping of how people get into positions of authority in the workplace and indicate how the effects of exogenous variables tapping qualifications are mediated by characteristics of jobs. Our ability to ascertain the extent to which women's and employers' behaviors affect the restriction of women from supervisory positions derives from the decomposition of the effects of job characteristics in these equations. That component due to composition on job characteristics could be due to either of two factors: women's or employers' behaviors. Some women may not desire positions with a lot of responsibility over the work of others. If this were the case, one might expect these women

² Some critics of this paper were uneasy with our measures of characteristics of jobs. For example, one argued that we ought to include major occupation groups or at least a dummy variable for whether the individual was in the census major group manager or not. Although we had considered this, the results of such models would, we thought, be tautological. Another critic felt that it was inappropriate to include prestige as one could argue that authority causes prestige. This argument is sensible if one uses occupational prestige to mean a measure of social honor. Here, we use occupational status as an attribute of the job which pertains to the "goodness" of that position. We are not concerned with social honor per se, but rather the extent to which the goodness of a job affects the likelihood of exercising authority. Clearly, these are different interpretations of the status and prestige metrics. Given the selection of status rather than prestige, and given that we interpret status as a characteristic of a job and not a measure of the general social standing of the individual, we feel that we are justified in including it in our models as prior to authority in the workplace.

to select positions which have a low probability of having any authority. For example, some women may choose female sex-labeled jobs with the expectation that they will entail few responsibilities which involve controlling the work of others. On the other hand, employers, because of their beliefs about women's ability to perform in supervisory positions, may direct or track females into positions which have little likelihood of involving supervision. Thus, the component of the sex difference in authority due to composition on job characteristics could be due either to women's or employers' behaviors. However, the job characteristics rates component is almost entirely due to the behavior of employers. If men get different amounts of authority than women for being in a high-status occupation, net of qualifications and sex-label of job held, then these differences must be due to the fact that employers are treating men and women disparately. Although we are not able to uniquely attribute portions of the sex gap in authority to the behaviors of employers and women, we can, through this decomposition, ascertain the relative importance of these two factors for the restriction of females from positions of authority.

In short, our regressions and subsequent decompositions will achieve two goals: (1) show the differential effects by sex of human capital, family characteristics, and job characteristics on the allocation of men and women into positions of authority; and (2) allow us to assess the relative importance of these three kinds of factors for the restriction of females from positions of authority.

Data, Variables, and Analytic Technique

Data. The data are from the Wisconsin Study of Social and Psychological Factors in Socioeconomic Achievements; this is a longitudinal study of a random sample of 10,317 persons who were seniors in Wisconsin high schools in 1957 (Sewell and Hauser, 1975). A follow-up study of the members of the sample was executed during 1975; completed interviews of 9,138 respondents (or 88.5% of the original

sample) were obtained. The data for these analyses are drawn from the 1975 follow-up interviews. Using this data set means that there are no individuals with less than 12 years of education included in the sample. The results cannot be generalized to non-high school graduates. Furthermore, we are investigating the distribution of authority at midlife (around age 37) and our results do not address the issue of the distribution of authority in the work setting for the total working population or for one cohort earlier or later in their life course. One could argue that by observing individuals at midlife, there does not exist sufficient variation in the dependent variable, as individuals might be more likely to have authority in the work setting later in their life course. This is not problematic as evidenced by the marginal distributions on the authority variables which are presented in Table 1.

The present analysis concerns 3,359 men and 2,254 women: (1) who were employed in the civilian labor force during the week of the survey in 1975; (2) who were not self-employed; and (3) for whom data were available on all-relevant variables. The largest sample attrition for females was due to the current employment restriction. Although information on authority was obtained for all individuals who had worked in the last five years, we could not construct the experience or ten-

Table 1. Means and Standard Deviations of Variables Used in the Analyses

ure variables for those who were not currently employed. It could be argued that, since women move in and out of paid employment, one could obtain a clearer picture of sex differences in authority by including in the sample women who had been employed during the last five years but who were not currently employed. An inspection of the distribution of the authority variables by current employment status for women indicates that women who are currently employed are much more likely to be in positions of authority in the workplace than were women who were not currently employed but had been employed during the last five years. This suggests that our exclusion of women who were not currently employed but did have recent work experience will result in an underestimation of the female disadvantage in authority in the workplace.³

We also have excluded self-employed people. Our three explanations related to why women as employees do not assume positions of authority within an economic organization. It should be noted that there are other ways to obtain authority in the workplace. Self-employed individuals who have others working for them have authority on the job. Men are more likely than women to be self-employed (U.S. Bureau of the Census, 1973; Wolf and Fligstein, forthcoming) and to have more authority if they are self-employed. Since the processes by which an individual obtains authority as an employee are probably quite different from the mechanism by which self-employed workers gain authority over others, we have decided to exclude self-employed people.

Variables. The dependent variables on authority in the workplace are derived from yes-no responses to the following set of questions:

- (1) I have authority to hire or fire others.
- (2) I can influence or set the rate of pay received by others.
- (3) I supervise the work of others, that is, what they produce or how much.

As earlier stated, these questions tap the amount of control over the work of others an individual has in the workplace.⁴ In our analyses, we treat these questions separately as dependent variables. Our decision to treat these as distinct aspects of authority was based on the conclusion that any scale combining these three aspects might mask or camouflage important sex differences in authority in the workplace. Having responsibility to hire and fire and/or determine pay represents a much higher level of authority than does having the responsibility of supervising others. It is probably the case that the processes by which people obtain these higher levels of authority are quite different from the manner in which people obtain these lower supervisory positions. In short, it is likely that women are discriminated against less in acquisition of positions with mere supervisory power than in their attainment of positions with more responsibility. Averaging these differences over level of supervision would not allow us to discriminate these different processes. Furthermore, different scaling options created methodological problems.⁵

³ It is also possible that the process of acquiring authority in the workplace differs for currently employed and those who are not currently employed but had worked in the last five years. In short, we may have a censoring problem (see Heckman, 1974, and Fligstein and Wolf, 1978, for discussion of this problem). It is reasonable to argue, however, that if those not currently employed but employed within the last five years were included, the differences between the parameters for the sexes would be more divergent than they are in our current analysis.

⁴ There is an extensive literature on authority in organizations (Weber, 1947; Azumi and Hage, 1972; Mechanic, 1962; Blau, 1964; 1968; Blau and Scott, 1962; Thompson, 1967; Crozier, 1964; Hall, 1972, to mention a few). This literature is mainly concerned with the levels of authority within organizations and in particular at what level various kinds of decisions are made (locus of control). Further this literature is interested in different dimensions of authority (or power). For example, distinctions between professional and bureaucratic authority, or traditional, legal, and charismatic authority are important. Our interest is not in the structure of organizations, but in the individual distribution of authority. From our point of view, it is also not critical to understand what the source of authority is (for example, is it professional or bureaucratic?), but rather our interest is in how much control an individual has.

⁵ Although these three variables form a Guttman scale, one could not assume that the scale was an interval one. Scales derived from factor analysis

Education is measured by the number of years of formal schooling completed *after high school*. Experience is measured by 1-Time Out, where Time Out is the proportion of months between high school graduation and the time of the interview when the respondent was known to be out of the civilian labor force. For males, we used detailed information on the timing of all levels of schooling, military service, and work in 1974 as a way to assign an individual's months as out of the civilian labor force. For females, additional information was used to code months as out of the civilian labor force: (1) did they work in every relevant interval between important life cycle events;⁶ (2) how long (in weeks) after the beginning of the interval did they return to work; (3) how long (in weeks) before the end of the interval did they quit working; and (4) how many hours a week did they work during the interval? The use of this additional information in constructing the experience measure for females results in a very good measure for them. Since this additional information was not available for men, we could not provide an exact equivalent for males. The measure for males slightly overestimates labor market experience since we must assume that men were employed when they were not in school or in the military. This is not an unreasonable assumption since a sample of predominantly white males with a high school education usually are employed quite regularly throughout their life course. It should be noted that utilizing this additional data for females when it is not available for men is much preferable to the

other two alternatives available to us. If we had utilized the well-known formula for experience, $AGE - SCHOOLING - 6$, we would have found that women had slightly more experience than men since age is fairly constant in the sample and women obtain less schooling than men do. If we had used only the information that we had for both sexes to assign months to not employed in the civilian labor market, we would have found that women had quite a bit more experience than men because of the schooling differential and the enormous sex differential in time spent in the military. Both of these options distort the data. Furthermore, since one of our goals is to attribute some of the sex difference in authority to women's employment histories, it is mandatory that we have the best available measure of experience. Our measure is clearly superior to the other alternatives available in this data set and to most of the other commonly used measures of experience for men and women.

Tenure is measured by the number of months from the time the individual first started working at the place of current employment to the time of interview minus the number of months during this period that the individual was known not to be working.⁷ The latter correction for time not working was made because females are more likely to have intermittent employment; it is possible that even though they started work with their cur-

were problematic because of the interpretation of standardized and metric coefficients. Interpreting metric coefficients is problematic since a one-unit change in the dependent variable has little intuitive meaning. Similar kinds of problems arise with the interpretation of standardized coefficients, especially when comparing across populations (i.e., the sexes).

⁶ The intervals were (depending on the number of live births): marriage to first birth, first births to second birth, second birth to third birth, third birth to fourth birth, next to last to last birth (if more than four children). We also have information on the interval end of last period to time of interview where end of last period was marriage for those with no children and the last live birth for those with children.

⁷ The tenure question harbors some ambiguities. The question is: In what month or year did you start working there? It appeared directly following a question concerning the name and place where he/she worked. The problem is that the word "there" lacks a referent. That is, it is unclear whether it refers to a geographical location or a parent firm. This ambiguity is not too problematic for females as their geographic mobility is restricted to some extent by their families and rarely will the women's occupational mobility result in the geographic movement of the whole family. For men, upward occupational mobility is often accompanied by geographic mobility from one establishment to another within a parent firm. If some men conceive of "there" as referring to local establishment, it is possible that time "there" (tenure) would be negatively related to positions of high authority, and tenure at firm may be underestimated. It is hard to judge the extent of this problem. However, it is reassuring to note that men's tenure levels are much higher than women's. Further, this ambiguity may arise only for a small number of men.

rent employer several years ago, they may have interrupted their employment. Thus, tenure measures the number of months worked at current place of employment.

Currently married is measured by a dummy variable which assumes a value of one if the person is currently married and a zero otherwise. This variable taps the extent to which the presence of a spouse (and the incumbent realities of his/her work) restricts access to authority in the work setting due to restricted geographical mobility and travel for work.

Children is measured by a dummy variable which assumes a value of one if the individual has had any live births and zero otherwise. We dichotomized this variable because it is not the number of children but the presence of a child which might restrict mobility of females.

Sex composition of the individual's occupation is tapped by two dummy variables. Male occupation is a dummy variable for whether the individual was in an occupation which is 0% to 14% female; unlabeled occupation is a dummy variable for whether the individual was in an occupation which is 15% to 74% female; the omitted category is female occupation (75% to 100% female). We used the 1970 Census of the Population Subject Report on Occupational Characteristics to determine the percentage female in each three-digit occupation. There are a variety of ways to operationalize sex-label of occupation. For example, Oppenheimer (1970) considers an occupation disproportionately female when the occupation contains a higher proportion of female workers than the labor market as a whole. For these analyses, we chose to designate highly sex-segregated occupations as male and female occupations and to include an unlabeled category which is quite heterogeneous with respect to sex composition.

Status is the occupational status (Duncan, 1961; Featherman et al., 1974) of the current job.

Analytical technique. In our analyses, we use multiple regression with a dummy dependent variable as well as decomposition techniques. Since the dependent variable is a dichotomy, the estimate of the dependent variable produced by the model can be interpreted as the probability

that an individual had that aspect of authority. There are problems using ordinary least squares when the dependent variable is dichotomous (Goldberger, 1964); these can be particularly problematic when the mean probability does not range between .25 and .75. We chose to use ordinary least squares for two reasons: (1) four of the six dependent variables have mean probabilities within the .25 to .75 range; and (2) various kinds of log-linear models presented other serious problems. One consequence of this decision is low R^2 values.

Results

Table 1 presents means and standard deviations on all variables in the analysis. From the first three rows, we can see the extent of the gross sex differences in authority. These sex differences are quite large: 28% of male employees have the responsibility to hire and fire others while only 8.8% of the women do. In terms of control over the pay of others the comparable figures are 37.4% (male) and 14.1% (female). Sixty and seven-tenths percent of the men supervise others while 37.8% of the women do. The absolute difference between the male and female means is about the same (.21) on all three dimensions. In short, women have much less authority as employees in firms than men do, regardless of what aspect of authority is considered. We shall not discuss the rest of the table except to say that the means and standard deviations of the explanatory variables are as expected.⁸

Table 2 presents parameters for Equation (1) (the reduced-form equation for each sex). The columns labeled *sex difference* are the results for regressions pooled for the sexes. The parameters in those columns represent the effects of the interaction terms between sex and the variables in the pooled model and thus

⁸ The sex differences in education are larger than are obtained from national cross-sectional samples (Treiman and Terrell, 1975; McClendon, 1976; Featherman and Hauser, 1976). This results from the fact that our sample includes only high school graduates. Women are more likely to finish high school but are less likely to complete each subsequent year (Folger and Nam, 1967).

* Significantly different from zero at the .05 level.

indicate whether the sex differences are statistically significant. These parameters indicate the total effects of human capital factors as well as the effects of family characteristics on the acquisition of authority in the workplace. As expected, the parameters indicate marked sex differences: Post-high school education is an important mechanism by which both men and women obtain authority, as witnessed by the size and statistical significance of its effects. Men and women obtain quite different authority returns on these investments, at least at higher levels of authority.⁹ In terms of gaining access to positions with the responsibility to hire and fire and/or determine pay, men receive about three times the return to each year of post-high school education than women do. For example, in the hire and fire equation, for each additional year of post-high school education, a man's probability of being responsible for hiring and firing others increases about 4% for each additional year whereas the comparable figure for women is 1.5. Similar patterns appear in the pay equation. Other than the fact that women get fewer payoffs for their schooling, these differences may reflect the divergent types of major fields of study chosen by men and women in post-high school education. For example, one would expect a man who majored in business to have greater access to a position of authority than a woman with a degree in nursing. Sex differences in returns to education do not appear in access to positions with mere supervisory power. Therefore, it appears that the lower the level of authority considered, the more egalitarian is the process of acquiring that level of authority, at least with respect to education.

The effects of experience are essentially similar across all aspects of authority. For men, experience has no effect on authority. There are two possible explanations for this lack of effect. First, the kind of interruptions in employment that could

affect men's acquisition of authority are not necessarily being tapped by our experience measure. Second, there is little variance in experience for men in our sample and in the population of white male high school graduates at large. In other words, males tend to work almost continuously and the only interruptions we measure (for education and military) do not affect their acquisition of authority in the workplace. Experience has substantively important, statistically significant, positive effects on all aspects of authority for women. If a woman had been in the civilian labor market all months from high school graduation until the time of interview instead of none, her probability of hiring and firing others would increase by .11, of having responsibility for pay would increase by .22, and of supervising others would increase by .30. The pattern suggests that experience has its largest effects on acquisition of lower levels of supervision. Although these effects are quite large, they are not as large as they seem, since a one-unit change in experience is the full range of the variable. The experience effect for women is probably due to the fact that: (1) increased work experience results in an increase in on-the-job training, which makes an individual more capable of assuming positions of responsibility; and (2) employers consider past employment history as a good indicator of women's current and future commitment to work in the paid labor force.

Tenure with current employer has quite different effects on authority for men and women. For women, tenure has a positive, statistically significant effect on each aspect of authority; however, these effects are not very large. A five-year increase in time with current employer increases the probability of hiring and firing or determining pay by .024; the comparable increase in the probability of supervising others is .048. For men, tenure with current employer only has a negative, statistically significant effect on the probability of hiring and firing others; however, the effect is very small such that a five-year increase in tenure reduces the probability of hiring and firing by .017. This small negative effect could be caused

⁹ By higher levels of authority, we mean ability to hire, fire, and determine pay. We discuss these together as these two equations appear remarkably similar for each sex. Clearly, our measures do not tap the highest levels of authority: the ability to make decisions concerning the creation and discontinuation of actual positions.

by two factors: (1) for men, highest level management positions often are filled from outside the firm rather than from within; and (2) the ambiguity of the question used to construct tenure for men who simultaneously experienced upward occupational mobility and geographical mobility (see fn. 7). In general, access to positions of authority in economic organizations is minimally affected (if at all) by tenure with current employer for men. However, for females, tenure with current employer has small effects on access to higher level supervisory positions and somewhat more of an effect on access to lower level positions of authority. The effects of tenure for women have two possible explanations: (1) women receive higher returns to on-the-job *firm*-specific training since higher level female managers often are produced from within rather than brought from outside (because of a presumed lack of qualified female managers); and (2) employers use length of service as an indicator of a woman's commitment to the employer and the paid labor force.

The two other variables in the reduced-form equations of Table 2 are whether the individual is currently married and whether the individual had any children. It is possible that women are restricted from positions of authority due to their limited geographical mobility and restrictions on travel for work purposes due to the presence of a spouse and/or children. There is no evidence for this, since each of these variables relating to a woman's family situation lacks substantively important effects on any aspects of authority. That these variables lack effects for females is neither surprising nor in conflict with earlier arguments. There are three ways in which the presence of children and marital status could affect women's access to authority: (1) women could be staying at home with children or being housewives, thereby reducing their work experience and job tenure; (2) women could be restricted in their ability to travel for work purposes or their geographic mobility could be limited by their spouses; and (3) other unspecified possibilities could be operating. Since tenure and experience are controlled in this equation, the vari-

ables indicating whether or not children are present and whether or not the woman is married would only have significant effects if the latter two factors were important. Although women's family factors may be related to their experience and tenure, they do not have any direct effects on authority.

The presence of children has a persistent nontrivial positive effect on each aspect of authority for men. This result is a bit surprising (but see Cramer, 1977, and Duncan et al., 1972). There are three possible explanations for this result. First, men with children may work harder because of the need to support additional individuals (Duncan et al., 1972:243). Second, men without children may be freer to consider other aspects of jobs besides earnings and power than are men with children. Third, the small group of men who have not had children by age 35 may be handicapped, ill, or may have spent a portion of their adult lives in institutions. All of these explanations are compatible with Cramer's (1977) finding that having a child positively affects a man's earnings, net of any increase in hours worked.

Table 3 presents a decomposition of the gross sex difference in different aspects of authority into three components: that due to compositional differences on human capital/family factors between the sexes; that due to differential rates of returns on

Table 3. Decomposition of the Authority Gap Using Only Human Capital/Family Factors

A. Responsibility to Hire and Fire Others		
Component	Gross	Percentage
Total	.192	100.0
Composition	.055	28.6
Rates	.149	77.6
Interaction	-.012	-6.2
B. Responsibility for Pay of Others		
Component	Gross	Percentage
Total	.233	100.0
Composition	.086	36.9
Rates	.212	91.0
Interaction	-.065	-27.9
C. Responsibility to Supervise Others		
Components	Gross	Percentage
Total	.229	100.0
Composition	.147	64.2
Rates	.192	83.8
Interaction	-.110	-48.0

human capital/family factors; and that due to an interaction between composition and rates. The males are used as a standard in this analysis. It should be noted that these decompositions are not unique as different standard populations could produce different results. Here, the choice of males as the standard was based on the fact that females have less authority than men and our interest is in seeing how the positions of females would be improved under different situations.

The purpose of this particular decomposition is to indicate the extent to which the restriction of females from positions of authority is due to their inferior qualifications. The extent of the sex difference due to this factor is measured by the component due to composition. This component indicates how much of the sex difference in authority would be alleviated if women had the same amount of education, experience, tenure, and the same family situations as men did but still had their own returns on these characteristics. Two-sevenths (28.6%) of the sex difference in the probability of hiring and firing others would disappear if women were as well-qualified as men on these factors; the comparable figure for the sex difference in control over pay is 36.9% and for supervising others it is 64.2%. The percentages of the sex difference in authority due to composition is nontrivial, suggesting that part of the reason women are excluded from positions of authority is their inferior qualifications. However, with respect to all three aspects of authority in the workplace, that proportion of the sex difference due to women's inferior qualifications is smaller than that due to differential returns on individual characteristics. Thus, even though the component due to women's inferior qualifications is significant, this is not the most important reason for women's restrictions from positions of authority. Last, the percentage of the sex difference that is due to women's inferior qualifications depends on level of authority; the higher the level of authority the smaller the percentage of the sex difference explained by women's qualifications. If women and men were equally well-qualified on human capital and family factors, women would still have very re-

stricted access to the higher level supervisory positions.¹⁰

The second half of our analyses allows us to assess the extent to which sex differences in authority are caused by women's and employers' behaviors. Table 4 presents parameters from equations predicting authority in the workplace where the independent variables are not only human capital/family factors but also certain characteristics of jobs. In our discussion of this table, we shall consider the two aspects of authority which represent upper level supervisory responsibilities together since patterns of effects are similar across these two aspects. Our discussion of these equations centers on two main issues: (1) the extent to which the exogenous variables are mediated by the characteristics of jobs; and (2) the differential effects of job characteristics.

In the equations predicting an individual's probability of hiring and firing or having control over pay, we find marked sex differences with the addition of job characteristics. Education has a statistically significant effect for men but not for women; about 70% of the effect of post-

¹⁰ It is necessary to assess the extent to which the component of the sex gap in authority that is due to women's inferior qualifications is over- or underestimated. There are two arguments suggesting that this component is overestimated and one suggesting that it is underestimated. First, because the decompositions are calculated from the reduced-form equations, they produce an upper bound estimate of the importance of composition on qualifications. This is because we are tapping the total effects of these variables; clearly, some of the effects are mediated by job characteristics. Second, since work experience may be slightly overestimated for men, the component due to composition on human capital/family factors is overestimated somewhat because if there were no measurement error, the mean on experience for men would be lower. The component due to composition could be underestimated as our measure of education does not tap the differences in the major areas in which men and women receive training. That is, part of the large differences in the effects of education on authority for men and women may be due to the fact that men (more than women) may choose college majors which increase their access to positions of authority. If measures of majors were included, the rate differences between men and women for years of schooling could decrease, and the composition differences in college majors could explain more of the authority gap between men and women. Thus, the differences due to composition could be underestimated.

* Significantly different from zero at .05 level.

high school education is mediated by job characteristics for men while all of the effect of education is mediated by these characteristics for women. This means that education is important in women's access to positions which involve high level supervision *only* because it helps to place them in jobs which have higher likelihoods of having these responsibilities. For men, however, post-high school education is not only important because it helps locate them in certain jobs that have high probabilities of having authority, but also because, net of job characteristics, men's educational credentials give them access to additional authority in the workplace. The effects of experience and tenure for females are only partially mediated (15% to 25%) by job characteristics; that is, net of the occupational status and sex-label of the job held, experience and tenure have, in three out of four cases, positive, small but statistically significant effects on the probability of having high amounts of authority. The fact that these effects persist suggests that regardless of position, additional experience and the implication of higher career commitment increase a female's probability of assuming positions with a higher level of authority.

In terms of access to positions involving high levels of supervision, the job characteristics included in the model have stronger effects for men than women. A ten-point increase in occupational status produces an increase in the probability of hiring and firing or determining pay of .06 for men. For women, the comparable result from a ten-point increase is .02 for the probability of hiring and firing and .03 for the probability of control over pay. Thus, in general, being in a higher status position increases a person's probability of assuming considerable control over the work of others. However, for each additional increment in status, the authority returns are two to three times larger for men than for women. This implies that, for men, being in a high status position often goes hand in hand with being in a position of authority, whereas for women, this is much less likely to be so. Of course, one could argue that this results from the fact that status measures

different things for men and women. For evidence that this is not the case, see Bose (1973).

We can also discern a general pattern of the effects of sex-typing of occupations on access to high levels of supervision. For both males and females, being in a male-labeled job (relative to a female one) and to a lesser extent being in an unlabeled job (relative to a female one) greatly increases an individual's access to positions of authority. These effects are quite large. For example, for males, being in a male occupation increases the probability of hiring and firing by .189; the comparable figure for an unlabeled occupation is .137. The effects of sex-label of job held are smaller for females; however, the sex differences are only statistically significant in the pay equation. These powerful effects of sex-label of job suggest that the concentration of females in female-labeled jobs is an important factor restricting females from positions of authority.

The differences in the processes by which the sexes gain access to positions with mere supervisory power follow the same general pattern as was found in the other two aspects of authority; we shall just highlight the main differences. First, 60% of the effect of education on the probability of supervising is unmediated by the characteristics of job position included in this model for women, whereas only 36% of the effect for men is unmediated. While the sex differences in the effect of occupational status are still large, they are not as large as they were in the case of higher levels of supervision. These two differences suggest that access to mere supervisory power is a bit more egalitarian than access to higher level supervisory positions. Sex-typing of occupation has no effect on the probability of supervising for either sex. Thus, the fact that women are highly concentrated in female jobs is not a good explanation for sex differences in supervision. Furthermore, these differences across dimensions of authority exemplify the necessity of inspecting each aspect separately.

Table 5 presents a decomposition of sex differences in different aspects of authority within economic organizations. The Appendix describes how these calcu-

Table 5. Decomposition of the Authority Gap Using Human Capital/Family Factors and Job Characteristics

	Hire-Fire		Pay		Supervise	
	Gross	Percentage	Gross	Percentage	Gross	Percentage

Interaction (J)	-.274	-142.71	-.123	-52.79	.093	40.60

lations were done. As earlier stated, this particular decomposition allows us to begin to assess the relative importance of the attitudes and behavior of women and the behaviors and policies of employers for the restriction of females from positions of authority. It should be noted that we view this as a first step in understanding the relative importance of these two factors. The component of the sex difference due to all aspects of human capital/family factors is not of much interest in this respect. It is only of interest to note that in models where certain characteristics of jobs as well as human capital/family factors are held constant, the amount of the sex difference due to human capital/family factors is much smaller than that due to characteristics of job positions. This merely indicates that the effects of exogenous variables are mediated through characteristics of jobs. In all instances, the component due to composition on human capital/family factors is positive since males have higher mean levels on these exogenous variables than females. For this particular model, the negative rates component of human capital/family factors arises when more of the effects of exogenous variables are mediated by job characteristics for men than for women. As discussed earlier, the decomposition of the influence of job characteristics allows us to ascertain the extent to which women's and employers' behaviors affect the restriction of women from positions of authority. That component due to composition on job factors could result from either women's or em-

ployers' behaviors. This is because women who are inhibited about taking positions of authority may choose job positions with little opportunity of obtaining authority. At the same time employers may direct women toward such job positions. The amount of the difference due to rates on job characteristics, on the other hand, is due almost entirely to the behaviors and policies of employers. If men get different amounts of authority than women for being in a high status occupation, net of human capital/family factors and sex-label of job held, then these differences must be due to the fact that employers are treating men and women unequally.

In Table 5, we note that the component due to the differences in composition on characteristics of jobs is nontrivial. This suggests that if women had the same mean occupational status and the same distribution on sex-label of job held as men, 22% to 40% of the sex difference would disappear. The job characteristics rates components are positive and quite large, suggesting that most of the sex differences in authority could be alleviated if women got the same authority returns to their job characteristics as men did. The component due to differential effects of job position factors is much larger (two to three times) than that due to composition on these factors. Although this is not a unique decomposition, this implies that the behaviors and policies of employers are a much more important explanation of the sex differences in authority than are the attitudes and behavior of women. One

could argue that the rates component is due in part to women's attitudes and behaviors. This is because women might get into positions of high status and income and yet not want to exercise the authority that is often demanded in such positions. The major implication of this is that some part of the job characteristics rates component may not be the result of employers' behaviors and policies. We argue that this is probably a minimal part of the job characteristics rates components since women who are inhibited about assuming positions of authority would not select positions which have a high likelihood of controlling the work of others.

Conclusions

There are two interrelated sets of conclusions that can be drawn from our analyses. The first relates to how men and women attain positions of authority in the workplace and the second concerns the extent to which sexual inequality in authority in the workplace is generated by our three potential explanations. Men are more likely to hire and fire, determine pay and supervise than women. The differential process of acquiring authority is quite complex, at least with respect to human capital/family factors. Men receive higher returns to certain human capital factors while women receive higher returns on others. With respect to job characteristics, it is clear that men get more authority for similar levels of occupational status and sex labeling of job held than women, at least in the access to higher levels of supervision. Further, the process of acquiring mere supervision is more egalitarian between the sexes than is the acquisition of higher levels of authority.

Our decompositions allowed us to ascertain the extent to which our three factors can explain the sex gap in authority. The amount of the sex gap that is due to women's qualification is nontrivial, but is, in all cases, less important than the attitudes and behaviors of women and the behaviors and policies of employers. While the subsequent decompositions do not allow us to identify uniquely the proportion of the authority gap that is due to women's and employers' behaviors, our

results suggest that the behaviors and policies of employers are much more important in the restriction of females from positions of authority. It should be realized that this is a first attempt to explore the sex differences in authority in the workplace. Clearly, a study of large firms which obtained data on employers' and women's attitudes and behaviors would be a relevant step in furthering our knowledge in this area.

The implications of these results suggest sorts of policies needed to produce parity between men and women in the distribution of authority in economic organizations. First, women should be encouraged to improve their qualifications. But this is not enough to alleviate the sex gap in authority in the workplace. More important, steps must be taken to alter the behaviors and policies of employers before women can reach parity with men with respect to authority in the workplace.

APPENDIX

CALCULATION OF DECOMPOSITION FOR TABLE 5

Given that:

$$\bar{A}_M = a_M + \sum_{i=1}^5 (b_{i(HM)} \bar{X}_{i(HM)}) + \sum_{j=1}^3 (b_{j(JM)} \bar{X}_{j(JM)}); (1A)$$

$$\bar{A}_F = a_F + \sum_{i=1}^5 (b_{i(HF)} \bar{X}_{i(HF)}) + \sum_{j=1}^3 (b_{j(JF)} \bar{X}_{j(JF)}), (2A)$$

where \bar{A}_M and \bar{A}_F are the means on authority for males and females; a_M and a_F are the intercepts for males and females; $b_{i(HM)}$ and $b_{i(HF)}$ are the parameter estimates (metric) for the effects of the human capital/family factors on authority for males and females; $\bar{X}_{i(HM)}$ and $\bar{X}_{i(HF)}$ are the means of human capital/family factors for males and females; $b_{j(JM)}$ and $b_{j(JF)}$ are the parameter estimates (metric) for the effects of characteristics of jobs on authority for males and females; and $\bar{X}_{j(JM)}$ and $\bar{X}_{j(JF)}$ are the means of the characteristics of jobs for men and women.

The total difference to be decomposed (A) is:

$$\bar{A}_M - \bar{A}_F. (3A)$$

The human capital/family total component (B) is:

$$(a_F + \sum_{i=1}^5 (b_{i(HM)} \bar{X}_{i(HM)}) + \sum_{j=1}^3 (b_{j(JF)} \bar{X}_{j(JF)})) - \bar{A}_F. (4A)$$

The human capital/family composition component (C) is:

$$(a_F + \sum_{i=1}^5 (b_{i(HF)} \bar{X}_{i(HM)}) + \sum_{j=1}^3 (b_{j(JF)} \bar{X}_{j(JF)})) - \bar{A}_F. (5A)$$

The human capital/family rate component (D) is:

$$(a_F + \sum_{i=1}^5 (b_{KHM} \bar{X}_{i(HF)}) + \sum_{j=1}^3 (b_{KJF} \bar{X}_{j(KJF)})) - \bar{A}_F. \quad (6A)$$

The human capital/family interaction component (E) is:

$$B - (C + D). \quad (7A)$$

The job characteristics total component (F) is:

$$(a_F + \sum_{i=1}^5 (b_{i(HF)} \bar{X}_{i(HF)}) + \sum_{j=1}^3 (b_{j(KJM)} \bar{X}_{j(KJM)})) - \bar{A}_F. \quad (8A)$$

The job characteristics composition component (G) is:

$$(a_F + \sum_{i=1}^5 (b_{i(KHF)} \bar{X}_{i(KHF)}) + \sum_{j=1}^3 (b_{j(KJF)} \bar{X}_{j(KJF)})) - \bar{A}_F. \quad (9A)$$

The job characteristics rate component (H) is:

$$(a_F + \sum_{i=1}^5 (b_{i(HF)} \bar{X}_{i(HF)}) + \sum_{j=1}^3 (b_{j(KJM)} \bar{X}_{j(KJM)})) - \bar{A}_F. \quad (10A)$$

The job characteristics interaction component is:

$$F - (G + H). \quad (11A)$$

The overall interaction component is:

$$A - (B + F). \quad (12A)$$

It should be obvious that whether one considers the intercept as part of the rates of human capital/family factors or characteristics of jobs is totally arbitrary. Since there were dummy variables in each set of variables, the intercept is the amount of authority a currently unmarried, childless individual in a female occupation has. Since it seemed arbitrary as to which rate it is, the intercept difference is, by default, included in the Total Interaction term.

THE ANTECEDENTS OF COMMUNITY: THE ECONOMIC AND INSTITUTIONAL STRUCTURE OF URBAN NEIGHBORHOODS*

WILLIAM L. YANCEY AND EUGENE P. ERICKSEN

Temple University

American Sociological Review 1979, Vol. 44 (April):253-262

This paper reports the results of an analysis of the institutional structure of 90 census tracts representative of the Philadelphia urbanized area. Ecological positions of the tracts and the social and economic characteristics of local populations are related to the number, type, and distribution of local facilities and services. An examination of the contribution of local facilities to residential stability of the census tracts indicates that the strong zero-order association between local institutional structure and residential stability is spurious, a result of the place of the tracts in the spatial and economic structure of the city.

The analysis of local institutions is an indispensable component of the sociology of urban neighborhoods. Local institutions, organizations and services are central characteristics of many communities (Foley, 1950; Jacobs, 1961; Gans, 1962; Warren, 1963; Hunter, 1975). Hawley (1941:629) noted that speculation on the question of the relationships between institutions and populations

has recurred from time to time in the literature of social science since the day of Adam Smith, but until recently no serious attempt has been made to investigate the relationships; a failure probably due to the lack of adequate data.

Several researchers have since examined some of the relationships between particular institutions and other aspects of the social organization of communities (Gans, 1962; Janowitz, 1967; Molotch, 1972). Local facilities are said to contribute to the stability and cohesion of neighborhoods by providing services, space and activities which are not only necessary for the development of an autonomous community, but also facilitate the development of informal networks among community members. A wide range of re-

search has documented the relationships between participation in organizations and institutions and the development of informal networks (Axelrod, 1956; Litwak, 1961; Breton, 1964; Nelli, 1970). Neighborhood facilities have similarly been shown to be related to the presence of informal networks of neighbors (Foley, 1950; Fried, 1963). Hunter (1975:544) reports that "informal neighboring . . . is positively affected by the degree to which residents use local facilities." While neighboring was related to the expression of a "sense of community" there was no direct relationship found between the use of local facilities and the sense of community (Hunter, 1975:544). Kornblum (1974:80) notes that in Chicago's South Side, "the tavern is among the most important of neighborhood institutions where people can form and maintain friendships with others whom they know well but may not associate with at home." Rossi (1955) has suggested that there is a reciprocal relationship between the stability of populations and facilities such as small grocery stores which depend on contact among residents. Jacobs (1961) argued that the viability and strength of urban areas is dependent on heterogeneous land use. Smith (1975:147), summarizing the major thrust of this literature, notes that

common use of local space may in and of itself be a relatively weak form of local cohesion, but it does reflect an important ecological orientation of local residents to the area

* Address all communications to: William L. Yancey; Department of Sociology; Temple University; Philadelphia, PA 19130.

This research was supported in part by a grant from the Center for the Study of Metropolitan Problems, National Institute of Mental Health (Grant #R01MH25244).

and an interdependence among them for the upkeep and maintenance of these facilities.

Despite this literature, there is reason to believe that hypotheses relating neighborhood stability and cohesion to the presence and distribution of local facilities and services may be false. Thus, although Boston's West End was clearly rich in local institutions, Gans (1962) points out that many were external to the peer group society and served principally as links between the local community and the outside world. The contribution of facilities to stability and cohesion of black communities is suggested by the contrast between the stable interdependent networks which Stack (1974) describes, without reference to a specific community institution, and the unstable friendship networks which were based in part on a corner food carry-out (Liebow, 1967).

We have shown elsewhere (Erickson and Yancey 1979b) that for the period between 1930 and 1970, industrial jobs within urban neighborhoods in 1930 increased their subsequent stability. Industrial neighborhoods characterized by relatively large proportions of working-class families whose breadwinners walked to work (Pratt, 1917; Duncan and Duncan, 1955) were more stable and more resistant to subsequent invasions of blacks. The stability of industrial blue-collar communities also is related to the interpersonal networks found there, i.e., relatively closed circles of local and interdependent friends and relatives (Young and Willmott, 1957; Gans, 1962; Fried, 1963; Kornblum, 1974).

It is also in the studies of the industrial urban villages where emphasis has been placed on local institutions as important antecedents of community stability and cohesion (Young and Willmott, 1957). The observed correlations between institutional development and residential stability may not be direct, but may reflect the socioeconomic character of the population and the position of the community in the larger social structure. The specific objective of this paper is to assess the contribution of local facilities and services to the stability of urban neighborhoods within the broader economic and social parameters which characterize them.

METHODS

Our research strategy was to list all nonresidential uses of space in a representative sample of 90 census tracts in the Philadelphia urbanized area. We then used census and other data to predict the presence and distribution of facilities within the 90 tracts and finally used structural and ecological variables along with measures of local facilities to predict residential stability.¹

Detailed listings of local facilities were obtained by an observer walking around each block in each tract and listing all nonresidential uses of space. The fieldwork was done in the spring and summer of 1975. A total of 11,685 facilities and services were recorded. Of these 1,359 were work places which did not provide goods or services to the local population. They have been eliminated from this analysis which focuses on the remaining 10,326 uses of urban space.

Each facility was initially classified into one of 316 detailed categories. Reliability checks, by independent observers and coders of 15 tracts indicated there was 80% agreement in the observations and coding, despite a six-month time lag between observations. The reliability tests indicated that there was considerable ambiguity between some of the original categories, e.g., luncheonettes, "take-outs," restaurants and bars.

For this analysis the facilities have been placed into eleven relatively broad

¹ This sample was designed for a household survey where equal numbers of interviews were desired from (1) the one-sixth of the Philadelphia Urbanized Area population living in the most residentially stable census tracts, (2) the one-third of the population living in census tracts which included the largest proportion of people who were of foreign stock, i.e., foreign birth or parentage, and (3) the remaining one-half of the population. Tracts included in the first, or *stability* stratum were those where at least 30% of the household heads had lived at the same address since 1949 or earlier. Tracts included in the second, or *ethnicity* stratum were those with less stable populations where at least 23% of the population was of foreign stock. The remaining tracts were designated to be the *control* stratum. Thirty census tracts were selected from each stratum. For the analysis given in this paper, tracts in the *stability* stratum were given one-third the weight of the *control* stratum tracts. *Ethnicity* stratum tracts were given two-thirds the weight of *control* stratum tracts.

categories. These are: *retail stores; small groceries; bars and restaurants; personal and household services*, e.g., barber and beauty shops, automobile repair shops and service stations, craftsmen, home services and repair; *professional services*, e.g., drugs and medicine, banking and finance, social services, funeral directors, business services, real estate, insurance and legal services; *clubs and associations; government services*, e.g., police and fire stations, mass transportation terminals, libraries, parks and recreation areas; *institutionalized churches; storefront churches; schools; and extralocal facilities*, e.g., universities, utilities, cemeteries and hotels which, while available to the local population, provide services to a larger geographic area.

In addition to recording the primary functions of the facilities, observers noted whether they provided space or settings for social gatherings. These were thought to be particularly important for the development and maintenance of social networks. Churches, recreation facilities, bars, restaurants, clubs and meeting halls are examples of gathering places.

Jacobs (1961) has argued that informal networks and neighborhood stability are facilitated by the physical integration of institutions and populations. In order to measure the degree to which the facilities were concentrated on a relatively few blocks as in a shopping center or commercial strip, we recorded the block location of each institution and calculated an index of institutional concentration. This index is the sum of the absolute difference between the proportional distribution of blocks and facilities in each tract divided by two. Thus a tract with all of its institutions located on two of its 100 blocks would have an index score of .98. By contrast, a similar tract with institutions scattered on 50 blocks received a score of .50. The index reflects, in part, the ratio of institutions to blocks in each tract. The correlation of $-.347$ between the number of institutions per capita and the index of institutional concentration indicates that census tracts with concentrations of facilities have relatively few of them.

These data were merged with information from the 1970 census. In addition to

the social and economic characteristics of the tract populations, the distance of each tract from the center of the city (city hall) and the distance from the nearest railroad were measured. These locational variables have been shown to have major effects on the location of commercial (McKenzie, 1933; Isard and Whitney, 1949) and industrial (Ericksen and Yancey, 1979b) activities, as well as the social and economic character of local populations. Age of the tracts was measured by the year in which 50% of the housing was completed. The measure of access to industrial employment is the number of manufacturing jobs within one mile of each tract in 1970. This latter is a modified version of the industrial work place potential developed by Duncan and Duncan (1960). Because of the highly skewed distribution of industrial concentrations, for this analysis this variable has been dichotomized at 5,000 industrial jobs. The measure of community stability used is the percent of the 1970 adult heads of households who had lived at the same address since 1949.

FINDINGS

Antecedents of institutional development. In Table 1 we have presented the standardized regression coefficients (beta weights) obtained between variables measuring the ecological character of the tracts and the socioeconomic character of local populations, and the number of each of the 11 types of facilities, the number of gathering places, the total number of facilities and their concentration. The independent variables used are the size of the local population,² the age of housing in the tract, the distance from city hall, the proportion of workers driving to work, the proportion of the tract's population that

² We decided to use the number of facilities as the dependent variables and the size of population as an independent variable instead of defining the dependent variables to be facilities per capita for two reasons. One was that we wanted to avoid the problem of interpreting a correlation of two ratios with the same denominator. The second reason was that we were substantively interested in variations in the relationships between size of population and number of facilities.

Table 1. Regression Analyses of Institutional Location: Beta Weights of Variables Which Were Significant at the .05 Level

Institutional Type	Population Size	Distance to City Center	Median Age of Housing	Pct. Workforce in Manufacturing	Pct. Drive to Work	Pct. Black	R ²

NOTE: All independent variables except distance to center of city obtained from 1970 census. City center was defined as Philadelphia City Hall.

was black and foreign stock, the proportion of families with annual income more than three times the poverty level, and the proportion of workers employed in manufacturing. Two independent variables, the percent of families with annual incomes more than three times the poverty level, and the proportion of population that was foreign stock, were not significantly related to any of the institutional characteristics. Thus they were eliminated from the analysis.

As can be seen from column one of Table 1, the number of most specific types of facilities, the number of gathering places and the total number of facilities in the tracts are related to the size of the population. In short, the more people there are, the more facilities are found. There are two exceptions to this general rule. Extralocal facilities, which provide services to larger geographic areas, and government services are not correlated with population. The latter are more frequently found in areas that are distant from the center of the city, where there are few blacks, and where few workers drive to work, i.e., in suburban-satellite municipalities.

In addition to the size of local populations, other variables which were significantly related to the total number of facilities and services are the age of hous-

ing in the tract, the distance from city hall, the proportion of the population that was black, and the proportion of workers who drove to work. As expected, given the literature describing the institutional character of older neighborhoods (Warner, 1968), the more recently developed census tracts have fewer facilities and services. Yet, despite the correlation between age of housing and distance from the center of the city, we also find that the distance of the tract from the center of the city is positively related to the total number of facilities and services. This somewhat surprising result is consistent with the previous work of McKenzie (1933) and Isard and Whitney (1949) who found higher levels of retail activity in areas which were more distant from major commercial centers.

The association between the proportion of the work force engaged in manufacturing and the total number of facilities is not significant. This result, not consistent with our initial expectations, concerning the character of working-class neighborhoods, suggests that there may be a considerable number of manufacturing workers living in the new blue-collar suburbs as well as in the older industrial neighborhoods. The only facilities positively associated with manufacturing workers are small groceries. Professional services,

i.e., lawyers, banks, business services, etc., are negatively associated with manufacturing workers.

The effect of the means of transportation to work is second only to population size in determining the institutional character of neighborhoods. Neighborhoods with large proportions of workers who use an automobile to get to work have fewer facilities than those whose workers use mass transit or walk to their jobs. Churches, schools, small groceries, and retail stores are not related to automobile use.

Perhaps the most striking finding of this research is the strong and negative effect of blacks on the number of facilities and services found in urban neighborhoods. This finding is consistent with the research of Aldrich and Reiss (1976) who showed that previously established businesses and services abandon areas which are invaded by blacks. Store front churches are the only local facility positively associated with high proportions of blacks.

We find that three variables, the distance from the center of the city, the age of housing, and the percent of the workers who drive to work are significantly related to the degree to which facilities are clustered in relatively few blocks in a given tract. The clear and unsurprising conclusion is that facilities located in new automobile suburbs are concentrated in commercial and service centers. Census tracts closer to the center of the city, and older ones in outlying industrial areas, i.e., those which were built before the widespread use of the automobile, are most likely to be characterized by the physical dispersion of facilities and residences.

Local institutions and residential stability. We now turn to the question of whether the presence of local facilities promotes community stability, or at least retards residential turnover. We see from the zero-order correlations in Table 4 that the relationship between institutional structure and population stability are in the expected direction and statistically significant in eight of the 14 tests and are in the expected direction 12 times. The relationship is particularly strong for retail stores, small groceries, bars and restaur-

ants and institutionalized churches. The relationships between stability and clubs and associations, professional services, storefront churches and schools are not significant. The number of extralocal institutions is negatively related to stability. Despite the weak association in several specific cases, the relationships between the total number of institutions, the number of gathering places, and the index of institutional concentration, indicate that neighborhoods with a large number of local institutions and those with institutions distributed across the tracts are more stable.

In order to test whether the relationship between the structure of local facilities and stability is spurious, we used the predictors of local facilities, along with predictors of stability in a multivariate analysis. Of specific concern is the possibility that institutional structure and stability may have common structural antecedents. Three regression analyses have been done. First, we have examined the contribution of a series of ecological, economic and social factors on the stability of neighborhoods. The structure of local facilities was omitted here. The independent variables included were: the age of housing in the tract, the distance from the center of the city and from the nearest railroad, the number of manufacturing jobs within one mile of the center of the tract, the proportion of workers employed in manufacturing, the percent using the automobile to get to work, the percent of family incomes over three times the poverty level, percent of housing which was owner-occupied, and the value of owner-occupied housing. In order to assess the effect of the structural and socioeconomic variables, independent of the age of the population, the proportion of the population over 65 years old was included as a control variable.

The second analysis focused upon the question of the contribution of local institutional development to the stability of the communities. We added our measures of local facilities to the equations predicting stability.

The third analysis examined the location of the black population in the city. In much of the literature on urban commu-

nity problems, the decline and instability of neighborhoods is used synonymously with the presence or potential presence of blacks. Previous research has indicated that the presence of industrial jobs and consequent presence of large numbers of manufacturing workers increased the residential stability of urban neighborhoods. The black population of Philadelphia has more than doubled in the last 30 years. Given this, coupled with the 125-year history of exclusion of blacks from industrial employment in the city (Erickson and Yancey, 1979a), we expected that the structural factors which were positively related to the stability of neighborhoods would have a direct and negative effect on the residential location of blacks.

The results of these analyses are presented in Tables 2 and 3. As can be seen, the residential stability of neighborhoods is a function of the age of housing in neighborhoods, the distance from railroads, the percent of the work force employed in manufacturing, the proportion of owner-occupied housing, and the age of the population. Other variables included in the analysis—the level of industrial employment nearby, the distance from the center of the city, the median value of housing, level of family income, and means of transportation to work—were not significantly related to stability.

Despite the traditional emphasis on the age of housing as a predecessor to their deterioration, decline, and subsequent instability, we find that the age of the census tracts is positively related to stability.

Even when the age of the population is controlled for, older neighborhoods are more stable than younger neighborhoods. Although the level of industrial employment was not directly related to stability, we find that two variables which are correlated with industrial location, railroad distance and manufacturing workers, are.

In the second series of regressions we added the number of each type of facility, the number of gathering places and total number of facilities per capita, and the index of institutional concentration to the equation predicting residential stability. Separate regressions were run for each institutional measure. We computed 14 separate equations, one for each type of facility, one for gathering places, one for all facilities and one for the index of institutional concentration. In Table 4 we have presented the standardized regression coefficients (beta weights) and percent increase in explained variance resulting from the inclusion of each of these variables. The results indicate that only two institutional variables are significantly related to residential stability—retail stores (the relationship is positive) and storefront churches (it is negative). All previously significant variables remain statistically significant. The overwhelming pattern obtained indicates that there is little or no association between the stability of local populations and the institutional character of neighborhoods, once their historical, economic and ecological character is taken into account.

The exceptions of retail stores and storefront churches may lead to the in-

terpretation that these institutions, unlike all others, have an independent effect on residential stability. We disagree. These statistical associations are the results of structural and ecological factors which affect the stability of neighborhoods, their racial composition, and their institutional character. Older neighborhoods which lack the structural basis for residential stability have been abandoned by whites and subsequently invaded by blacks. Aldrich and Reiss (1976) have shown that in such neighborhoods white-owned retail shops are closed. We have seen similarly in Table 1 that black neighborhoods

have fewer retail stores and more storefront churches.

With the final two equations in Table 3 we examined the relationship between factors related to the residential stability of neighborhoods and the location of blacks in the city. One uses the basic model predicting the stability of neighborhoods to predict the location of blacks. In the second we have added the number of industrial jobs, a primary theoretical variable which was not significantly related to stability, to the equation. The general hypothesis was that those structural factors which were positively related to the stabil-

¹ The variables are as defined in Table 1, divided by census tract population.

² Fourteen equations were computed, successively adding the facilities per capita variables to equation (1), Table 3. All variables which were significant in equation (1) were also significant when the facilities per capita variables were added.

³ This is the increase over R² = .666 given in equation (1), Table 3.

ity of neighborhoods would be negatively related to the presence of blacks. The results obtained from these analyses indicate that this is the case with one notable exception. The age of housing is not only related to stability, but is also the single best predictor of the location of blacks in the city. The relationship is positive in both cases. The second equation shows that access to industrial employment is negatively related to the presence of blacks. Including industrial access resulted in reducing the effects of railroad distance below statistical significance. Neighborhoods which have become dominated by blacks are the older and abandoned industrial areas and streetcar suburbs, rather than the stable industrial urban villages or new automobile suburbs. In more general terms, these results confirm the observation made by Schnore (1964:336) that "the 'marginal work force' may be physically marginal to a given industrial community."

SUMMARY AND CONCLUSIONS

There are some obvious limitations to this research. There is no measure of the size or level of institutional activity. A small corner grocery has been equated with a large suburban supermarket. The weak association between the level of income and the number of institutions found in this study contrasts sharply with the previous work of Hawley (1941) and Cuzort (1955) who reported income levels associated with the level of institutional activity. This difference may be due to the lack of information on institutional magnitudes in the present instance.

However the results conform to Hawley's (1941:630) statement that "the way in which a population lives is reflected in the institutions which serve it." Previous research (Foley, 1950; Fried, 1963; Gans, 1962) indicates that working- and lower-class populations depend on local institutions. Stable working-class communities have the highest levels of institutional integration, the largest number of local institutions and the largest number of gathering places. The institutional structure of these neighborhoods reflects the

life styles of their populations, in particular high levels of interdependence between nearby friends and relatives. By contrast, the sparse institutional structure of the newer suburbs and concentration of institutions in shopping centers reflects a more mobile, cosmopolitan life style (Berger, 1960; Gans, 1967).

The relative absence of facilities and services in black neighborhoods remains even after controlling for factors which were assumed to account for differences in the institutional completeness of black and white communities. Blacks, with fewer local facilities, are dependent on public transportation for many services. This suggests an additional dimension to the reality of racial discrimination in American cities.

Perhaps the most surprising result concerns the relationship between local institutions and residential stability. Zero-order relationships between the number and integration of facilities in local communities and their residential stability disappear when other structural variables are controlled. Critical to the understanding of the stability of urban neighborhoods appears to be their economic character—particularly the location of industry, and the characteristics which are associated with industrial workers and their communities. Blacks in Philadelphia are concentrated in the oldest areas of the city. This finding taken alone may be interpreted in terms of the traditional argument of the "natural cycle" of neighborhood growth and decline. Yet we find that there are important exceptions to this general rule. Neighborhoods which are near railroads, have access to large numbers of industrial jobs, and are characterized by high proportions of industrial workers and homeowners, remain stable despite their age. It is the nonindustrial areas which are most vulnerable to abandonment and subsequent invasion by blacks.

In recent years several authors have documented the decline of local community autonomy (Vidich and Bensman, 1958; Warren, 1963). Not only are individuals more mobile, but decision making is more centralized and institutions more interdependent. As Warren (1966:vi) has written:

The strengthening ties of community units to extra-community systems orients them in important and clearly definable ways toward larger systems outside the community, making the model of a somewhat delineated, relatively independent and self-sufficient community less and less relevant to the modern scene.

Although the degree to which these local institutions are controlled by external systems is not known, results of this analysis have direct implications for Warren's discussion and the recent debates concerning the loss of community in urban areas (Luloff and Wilkinson, 1977; Hunter, 1977). If we take the presence and distributions of facilities as an indication of a community's *internal* structure and the place of the community in the city's economic structure (particularly its access to industrial employment) as an indication of *external* institutional linkages, the implications are clear. The latter are of primary importance in determining the internal structure, i.e., the social and economic character of local populations, the type and number of local institutions, and the degree to which a community is residentially stable. Paradoxically, communities having specialized and direct links to the larger industrial economy are characterized by the highest levels of stability and internal cohesion.

RACE, REGIONAL LABOR MARKETS AND EARNINGS*

TOBY L. PARCEL

University of Iowa

American Sociological Review 1979, Vol. 44 (April):262-279

Despite continued interest in racial inequality, studies which effectively integrate structural and socialization/investment explanations of racial differences remain rare. In this paper arguments are presented for using contextual analysis to study individual labor earnings as a function of both background/investment variables and specific dimensions of areal labor market social and economic organization. Analysis from samples of workers (821 whites, 375 blacks) suggests that, in the presence of numerous controls (1) black earnings levels are hindered by racial competition and residential segregation, and facilitated by export sector productivity; and (2) white earnings levels also are hindered by residential segregation, but facilitated by racial competition and export sector productivity. Implications of these findings are explored with regression standardization which suggests that policy seeking to promote racial economic equality must recognize that changes in the racial distribution of resources would *not* occur independently of changes in the rates of return to resources.

Continued interest in explanations of racial differences in economic outcomes (Farley, 1977; Featherman and Hauser,

1976b; Kluegel, 1978) is prompted both by continued gaps between racial groups in socioeconomic status as well as by theoretical developments in the field of stratification itself. In particular, recent arguments concerning the importance of labor markets as determinants of socioeconomic status (Hanushek, 1973; Stolzenberg, 1975; Althausen and Kalleberg, 1977; Spilerman, 1977) reflect renewed interest in structural explanations of inequality. Congruent with this emphasis, in this paper I direct attention towards a relatively neglected structural determinant of individual labor market earnings: the regional labor market in which a worker is employed. In order to develop an appropriately specified model of earnings attainment for blacks and whites, I argue that integration of the two major traditions

Preston and Hubert M. Blalock, Jr. provided helpful comments on an earlier draft. Charles W. Mueller and two anonymous referees provided additional helpful comments. Thanks are due to Alan T. Richards, Marie Baker-Lee and Debra K. Shaffer for computer programming, clerical and computational assistance, respectively. The remaining errors are my own.

which previously have been utilized to study racial inequality is theoretically advisable and empirically feasible.

PREVIOUS STRATEGIES AND SUGGESTED SYNTHESIS

Sociologists and economists interested in racial inequality have employed one of two types of models. Studies of individual black-white economic differences which fall within the rubric of the status attainment tradition (Duncan, 1968; 1969; Coleman et al., 1972a; Blum, 1972; Siegel, 1965) direct attention to factors such as family background, years of education and occupational status or prestige as determinants of earnings. These studies suggest that both lack of access to key resources (e.g., education, family background) as well as racial differences in rates of return to these resources contribute to racial economic status differences. Research within the human capital tradition similarly emphasizes the importance of individual investments such as education, migration and job experience as earnings determinants (Weiss and Williamson, 1972; Blinder, 1973; Weiss, 1970; see Mincer, 1970, and Blaug, 1976, for general reviews). Illustrating the second approach is ecological research analyzing structural determinants of black-white ratios in economic status, or of minority status itself. Analyses of occupational competition/segregation (Snyder and Hudis, 1976; Szymanski, 1976) and areal determinants of economic outcomes (Master, 1975; Spilerman and Miller, 1976) are cases in point.

Although these traditions emphasize socialization or structural explanations of achievement, their mutual focus on inequality provides commonality. One is surprised to find, then, that studies which integrate elements from each tradition have been rare. The advantages of such integration would seem obvious. It is clear that both socialization/investment and social structure will influence individual socioeconomic status; only with an effective empirical integration can we assess the extent to which each type of explanation is useful. Considerations of par-

simony also are served if such an integration can be accomplished.

Empirical problems, however, seem to have prevented development of models which incorporate good indicators of both structural and socialization explanations of attainment. For example, analyses by Harrison (1972) and Wachtel and Betsey (1972) incorporate dummy variables representing SMSA and industry affiliation (Harrison) and area, industry and job (Wachtel and Betsey) into wage attainment models; they evaluate the relative importance of these "structural" variables over human capital variables (education, health, etc.) in predicting earnings. Kalachek and Raines (1976) adopt a similar strategy.

Harrison and Wachtel and Betsey cite dual labor market theory as the basis for their empirical work, yet the reader is left wondering whether this theory actually has been tested. When Harrison reports that industrial affiliation and area "make a difference" in earnings attainment, we remain uncertain as to what *specific dimensions* behind these categories actually contribute to the observed effects. In terms of evaluating structural explanations for achievement, these types of findings are less intellectually satisfying than those produced by ecological analyses which actually incorporate specific dimensions of social organization suggested by theory (Jobu and Marshall, 1971; Spilerman and Miller, 1976; Masters, 1975). These ecological studies, however, evidence a complementary deficiency. While inclusion of indicators of concepts theoretically operative at an aggregate level is facilitated due to usage of an ecological unit of analysis, measurement of individual-level characteristics and processes necessarily suffers. This defect is a particularly serious one given that both the human capital and status attainment literatures provide clear evidence that individual investments and socialization experiences importantly affect economic outcomes. By definition, ecological analyses only indirectly can measure these concepts, and hence run the risk of generating estimates of "returns" to structural factors which are biased.

The solution to these problems which I

utilize in this analysis represents an attempt to incorporate the advantages of each of these types of approaches while avoiding their respective disadvantages. The models I estimate are contextual models which retain the individual as the unit of analysis while incorporating independent variables from both the individual and the ecological levels of analysis. The dependent variable is labor earnings of individual workers; independent variables reflecting investments in human capital and socialization factors are measured at the individual level. Variables incorporated to tap variation due to labor market conditions are interval-level measures of characteristics specific to the areas in which workers reside. Such a strategy has the advantage of measuring variables at the level of aggregation at which the constructs are theoretically operative, thus maximizing their potential explanatory power. Each "type" of variable thus serves as a well-measured control for the other. This strategy avoids weaknesses evident in analyses of racial inequality derived from the status attainment perspective which omit indicators of social structure and therefore must indirectly infer their operation; it also avoids the pitfalls of ecological analyses which measure individual investments such as education at an aggregate level (e.g., Masters, 1975) and which are forced to omit other relevant indicators of socialization experiences altogether due to measurement problems. In addition, it represents an improvement over studies which note associations between individual outcomes and dummy variables representing categorical membership. More specifically, given that others have demonstrated that areal affiliation "makes a difference" in earnings attainment (e.g., Harrison, 1972; Wachtel and Betsey, 1972), this analysis seeks to explain *why* such findings exist.¹

In order to delimit the analysis, I have chosen to focus upon areal labor market characteristics as the structural variables

of interest. Several reasons suggest that this focus is a needed one. First, areal variation in the relative economic status of blacks and whites raises questions concerning the areal characteristics which may be responsible for this variation. Second, as I will indicate below, there are several well-developed literatures which argue for the importance of regional influences on status attainment, and thus provide a basis for model specification. Third the study of regional labor markets may be viewed as a necessary complement to recent analysis of occupational labor markets (Stolzenberg, 1975; Althausser and Kalleberg, 1977; Spilerman, 1977). Given theoretical arguments concerning the interrelationships among occupational, areal and industrial markets functionings (Thompson, 1965; Spilerman, 1977; Althausser and Kalleberg, 1977; Harrison, 1972; Lane, 1972), analysis of each type of labor market in isolation from the rest prepares the foundation for theoretical and empirical integration.

Estimation of contextual models requires a developed theoretical framework. Deliberate avoidance of dummy variables representing areal labor markets in favor of a strategy attempting to ascertain why location of employment is important demands a theory to that effect. Below I argue that characteristics of both the social and economic organization of areal labor markets influence earnings attainment of blacks and whites.

THEORETICAL CONSIDERATIONS

The basis for arguments concerning the impact of areal *economic organization* upon individual earnings is presented by Thompson (1965) in *A Preface to Urban Economics*. His theory of urban economic functioning takes as its premise the operation of a local labor market which affects local income distribution via economic activity in the export base. He argues that an urban area is not unlike a small industrially-oriented nation which must export products to survive economically. Thus, he argues for usage of the urban area (SMSA) as the unit of analysis; it is seen as a potentially viable economic unit which devotes as much as one-half of its

¹ Alexander and Eckland (1975) suggest that such categorical variables representing affiliation may mask offsetting tendencies in the operation of two or more variables associated with affiliation. Contextual analysis avoids this problem.

economic activity to the production of goods for export. Economic activity within the export sector influences the areal economic welfare. In particular, wages in the dominant export sector will influence wages for other jobs in that labor market, i.e., an "intraarea wage roll out" effect will occur. This reasoning assumes that the local labor market is autonomous, and that migration between labor markets is sluggish. From this hypothesis it follows that the local service sector must offer wages which are at least partially competitive with the dominant export sector industries, or they will face problems in recruiting workers. Thus, a high-wage export industry directly enriches its own workers by paying them high wages, and indirectly enriches other workers by raising wages in the local service sector through intraarea competition (Thompson, 1965:73).

Thompson also argues that a strong export sector should contribute to reduced income inequality through several mechanisms. First, a strong export sector is composed primarily of core as opposed to peripheral firms;² hence unionization will be extensive and promote earnings equality among these workers. Second, predominance of manufacturing activity constricts the skill range of occupations relative to what would obtain in a diversified economy. In manufacturing most available jobs are those in mass production while more diversified economies demand higher proportions of both high and low skill jobs in a variety of service industries. Third, strong export sectors are generally composed of firms owned by individuals who live outside that export sector, particularly in big cities. Hence income from property plays a minor role as a source of income to community residents since industrial profits go elsewhere. We note, however, that his evidence concerning the impact of the export sector upon racial economic inequality is largely indirect.

While a complete test of Thompson's ideas is beyond the scope of this analysis, one of his central hypotheses is that wage

levels in the export sector will influence wage levels throughout the labor market. In this analysis I suggest that manufacturing wage levels in an areal labor market will affect individual earnings levels of blacks and whites, independent of investments such as education or job experience. Hence areal manufacturing wage levels will be used as an indicator of labor market productivity which affects workers' wages. Additional analyses by Franklin (1968), Reder (1955), Turner (1951) and Masters (1975) provide supporting theoretical rationale and evidence for such a conceptualization.

Additional analyses suggest that areal labor market *social organization* should influence workers' economic standing. Several researchers have investigated the relationship between residential segregation and racial income inequality, but findings remain contradictory. Masters (1975) presents evidence which suggests that residential segregation is not associated with black-white earnings ratios net of racial ratios of years of education, areal unemployment rates, and indicators of industrial structure for 77 large SMSAs in 1970. Analyses by Kain and Persky (1969), Mooney (1969) and Kain (1968), however, argue that residential segregation limits blacks' employment opportunities. They argue that residential segregation is pervasive, and there are employment opportunities which blacks miss because the sheer size of metropolitan areas constitutes an obstacle both to acquiring information concerning jobs and to reaching places of employment once jobs have been secured. The trend towards "suburbanization" of employment has removed and will continue to remove jobs from the central cities where the majority of blacks live, thus exacerbating the problem. In terms of policy implications, these findings suggest that eliminating residential segregation is a key step to improving black employment opportunities and thus economic status.

Due to the presence of conflicting findings in this field, I will include a measure of this construct in the analysis. The literature is explicit in suggesting that residential segregation should negatively affect black economic status. To the extent that

² Thompson does not phrase his arguments in dualist terms, but these labels provide an accurate reflection of his ideas.

whites benefit from exclusion of blacks from employment opportunities, we would expect the partial slope of earnings regressed on residential segregation to be positive for whites.

A second dimension of labor market social organization which has received theoretical and empirical attention is that of racial competition for economic opportunities. Most of the analysis has focused upon the explication of the negative correlation between the percent of nonwhites or women and income level within an occupation as a function of occupational competition and/or occupational segregation (Hodge and Hodge, 1965; Taeuber et al., 1966; Snyder and Hudis, 1976; Szymanski, 1976). Theoretical works by Blalock (1967), Thompson (1965) and recent empirical analysis by Spilerman and Miller (1976) suggest that a similar conceptualization can be made for geographical units. Blalock argues that nonlinear increases in minority concentration can lead to economic discrimination by whites due to their perception of black threats to white levels of resources. I incorporate an indicator of racial competition in the analysis; I predict that high levels of black concentration will be negatively associated with black earnings, independent of the remaining determinants. The prediction concerning the influence of such levels of minority concentration among whites is more ambiguous. While Blalock's analysis would suggest that whites benefit from the economic discrimination against blacks, empirical analyses addressed to this question have provided mixed findings (Glenn, 1963; 1965; Bergmann, 1971; Szymanski, 1976; Snyder and Hudis, 1976). The bulk of the findings from previous analyses of occupations suggest that white gains from black poverty may be minimal; however, evidence from Spilerman and Miller's recent analysis of geographical areas indicates that whites may benefit economically from racial competition in a labor market. A positive coefficient among whites would suggest that whites economically benefit from black concentration in areal labor markets, while a negative coefficient would indicate that

whites suffer economically from such concentration.

METHOD

A sample of respondents from the 1972 Michigan Panel Study of Income Dynamics (PSOID) (Survey Research Center, 1972) was utilized in the analysis. Included are all black and white males aged 35-54 whose areas of current and former residence could be identified, who were not employed in the armed forces in 1972, and who reported earnings for 1971. The age range of the sample was limited to a 20-year cohort in the "prime" of their working years to eliminate cohort effects as noted by Price (1969) and Lieberman (1973). Application of these criteria yielded samples of 375 blacks and 821 whites.

Measures of individual-level characteristics were taken directly from the PSOID data file and included as indicated below. Ecological characteristics representing the social and economic organization of areal labor markets were produced from several sources as outlined below and attached to individual cases according to the following criteria. Respondents' areas of current residence were identified by utilizing respondents' answers concerning the states and counties of current residence. If the county of current residence was part of an SMSA in 1972 according to the 1972 Census of Manufacturers, I classified the respondents as living and working in that SMSA, assumed that contextual variables at that level of aggregation would be theoretically causative, and measured the ecological characteristics on the basis of that classification. If the county was not part of an SMSA, I assumed that the county was the theoretically causative aggregative unit, and measured the ecological variables on the basis of the county. Thus the ecological variables describing the current area of residence are measured on the basis of the SMSA or the county, depending upon the respondents' current county of residence. Ninety-nine SMSAs and 87 counties are represented in the samples.

Variables incorporated in the analyses

include (1) individual-level indicators of investment in earnings potential and of socialization experiences; (2) aggregate measures of areal labor market economic and social organization; (3) additional control variables representing socialization experiences not directly tapped by the remaining indicators.

Dependent Variable

Earnings. Respondents' 1971 total labor earnings include earnings when employed by others, income from self-employment, and other income derived from respondents' own labors. The earnings measure was deflated according to an interarea wage deflation factor for 1972 produced by the U.S. Bureau of Labor Statistics (1973) in order to control for variations in the cost of living across regions.

Independent Variables

Individual-level variables. *Occupational prestige* was measured by Siegel's (1971) prestige sources for major occupational groups (e.g., professional, managers, craftsmen and foremen) which were provided on the PSOID files. *Education* was coded in dummy variables to reduce specification error due to the nonlinear relationship between education and earnings. The breaking points utilized to create the dummy variables for both education and weeks worked are taken from Weiss and Williamson (1972), and reflect delineations of portions of the respective functions which are expected to be approximately constant on the basis of theory. For example, while the relationship between nine to eleven years of education and earnings is expected to be approximately constant, an increment in earnings due to high school graduation is expected and hence that period of attainment is dummied separately. Such a strategy is designed to maximize the variation in earnings explained by education. The categories are: 6–8 years, one, zero otherwise; 9–11 years; 12 years; 12 years plus other training or some college; college graduate; college graduate plus graduate degree or graduate work.

Weeks worked was similarly coded in dummy variables: 14–26 weeks, one, zero otherwise; 27–39 weeks; 40–47 weeks; 48–49 weeks; 50–52 weeks. *Experience in the labor force* is estimated by subtracting years of schooling attained plus seven from age; thus following Mincer (1974) and others, we assume that labor force experience begins when schooling ends and experience should be positively related to earnings.

Migrant is a dummy variable coded one if the respondent currently resides in a state different from that in which he grew up. This variable is included as a control for social selection which may pose a threat to the internal validity of contextual analyses (Hauser, 1974). *Health limiting work* is a dummy variable coded one if the respondent reports a health impairment which limits either the type or duration of work he can perform, zero otherwise. Following human capital analyses which regard workers' investments in health as investments in earnings potential, I include this variable as a control; it is expected to be negative in sign.

Ecological variables. *Wages per man hour* is the ratio of the wage bill in the manufacturing sector to the number of man hours worked in that sector. This measure was produced from the 1970 Census of Manufacturers Area Series (U.S. Bureau of the Census, 1975) according to the labor market of current residence. It is included as an indicator of export sector productivity, and, following Thompson's (1965) arguments concerning export sector wage levels affecting urban wages generally, is expected to be positive in sign. *Unemployment rate* was produced from the U.S. Bureau of the Census (1975) according to the labor market of current residence and incorporated as a control variable, an additional indicator of labor market productivity; it is expected to be negatively associated with earnings. *Percent black* was included as the indicator of racial competition. It was produced from the 1970 Census of Population and calculated as the ratio of the number of black to the total population in the labor market following Blalock (1967). I used the natural log of this ratio to correct for no

Table 1. Means (or Category Percentages) and Standard Deviations of Variables Utilized in Analysis

Variable	Whites		Blacks	
	\bar{X} or %	S	\bar{X} or %	S
Deflated Earnings, 1971 (in dollars)	\$12,432	(7198)	\$7,904	(4436)

College Graduate	12.9%	(33.5)	.40%	(6.14)
College Graduate and added schooling or higher degree	7.87%	(26.9)	2.3%	(16.7)
Years of Education (interval scale)	12.2	(3.57)	9.03	(3.93)
Weeks Worked, 1971: 0-13	2.76%		9.91%	
14-26	1.93%	(13.8)	2.50%	(15.63)
27-39	5.82%	(23.4)	8.23%	(27.5)
40-47	18.5%	(38.9)	22.3%	(41.7)
48-49	32.5%	(46.8)	21.9%	(41.4)
50-52	38.5%	(48.7)	35.2%	(47.8)
Weeks Worked (interval scale)	46.23	(8.91)	42.96	(13.64)
Occupational Prestige	41.8	(13.4)	28.9	(12.4)
Work Experience (in years)	25.2	(6.77)	28.0	(7.73)
Health Limits Wk.	8.65	(28.1)	13.8	(34.5)
Unemployment Rate	3.87	(1.53)	3.43	(1.23)
Wage per Man Hour (in dollars)	3.98	(.79)	3.81	(.85)
Segregation Index	84.7	(6.26)	87.7	(5.40)
Lifetime Migrant	29.7%	(45.7)	46.4%	(49.9)
Percentage Black (natural logarithm)	1.53	(1.56)	2.88	(.681)
Work Motivation	9.22	(2.63)	9.07	(2.76)
Mental Ability	10.22	(1.80)	8.42	(2.49)
Father's Education	8.01	(3.48)	5.80	(3.30)
	(N=821)		(N=375)	

linearity. It is expected to be negatively associated with earnings for blacks, but potentially positively associated with earnings for whites. *Segregation index* was included as the indicator of residential segregation. It was produced by Sorensen et al. (1974) and attached to 65% of the black cases and 45% of the white. Thus although there was a substantial proportion of missing cases for this construct, due to its theoretical importance it was included in the analysis. Care will be taken to evaluate its statistical significance by using appropriately reduced N's in the tests. Signs of the coefficients are predicted to be negative for blacks and potentially positive for whites.³

Additional control variables. In a sec-

³ These contextual measures are best viewed as global variables (Lazarsfeld and Menzel, 1969) which are reflective of emergent properties of aggregates. In no case will I include an analytic variable with its individual-level counterpart in the same equation since this strategy biases the findings in favor of the analytic variable, i.e., that with the lesser amount of measurement error (Hauser, 1974).

ond specification of the earnings function, I incorporate a number of additional control variables representative of socialization experiences and individual investments not tapped directly by the aforementioned indicators; they are all expected to be positively associated with earnings. *Father's education* is a scale of educational attainment constructed by coding the midpoints of the categories outlined above for the respondents' education, as follows: 0-5 years=3; 6-8 years=7; 9-11 years=10; 12 years=12; 13-15 years=14; college graduate=16; beyond college graduate=18. *Work motivation* was computed by summing respondents' scores on 16 questions asked by Michigan Survey Research Center specifically to tap work motivation. *Mental ability* was computed by summing respondents' scores on a 13-item sentence-completion test included in the 1972 SRC survey.

RESULTS AND DISCUSSION

Table 1 presents the means and standard deviations of the variables utilized in

this analysis for both the PSOID blacks and whites. Blacks evidence lower levels of earnings and occupational prestige than do whites, obtain lower levels of educational attainment than do whites and work fewer weeks per year. Blacks are more likely to be subject to health limitations than are whites, obtain lower scores on the mental ability and work motivation measures, and to have fathers with lower levels of educational attainment. Blacks are also more likely to be lifetime migrants.

We also are interested in ascertaining the level of ecological resources to which blacks and whites are exposed. Since the ratio of black to white residents varies by area, we expect to find some differences in the access to areal labor market resources by race. Concerning ecological characteristics, blacks are slightly more likely to live in residentially segregated areas, to live in areas which pay slightly lower manufacturing wages, and more likely to live in SMSAs or counties with high proportions of black residents.⁴ However, they also are located in areas which have slightly lower levels of unemployment.

Table 2 presents two specifications of an earnings function which are estimated using analysis of covariance. Equation 1 includes the education and weeks worked dummies, indicators of occupational prestige, work experience, health limitation, lifetime migration and the four ecological variables representing social and economic organization of the labor market of current residence. Deviations from the mean are presented in place of unstandardized regression coefficients for the education and weeks worked constructs.⁵ The findings suggest that while

most of the human capital variables are statistically significant and positive, the ecological variables also influence earnings for both blacks and whites. At the lower educational levels whites are more handicapped relative to the mean white educational attainment than are blacks relative to the mean black educational attainment. At the upper levels of educational attainment whites obtain somewhat higher returns to schooling than do blacks, provided one takes the respective mean levels of attainment into account. Concerning weeks worked, the pattern evident at the lower educational levels is repeated: whites are relatively more handicapped at these levels than are blacks. With the exception of the 48-49 weeks increment, however, this pattern is continued at the upper levels as well.

While the health limitation and experience coefficients evidence the appropriate signs, they are not statistically significant; the experience effects may be reduced due to the limited cohort which comprises the sample. Finding the occupational prestige coefficient significant for blacks but not for whites may be due to the substantial effects which education has among whites, thus reducing the role of occupational prestige in the earnings attainment process.⁶ Migration is significant for

blacks and whites addition of each of these sets of variables resulted in increments to explained variance significant at less than the .001 level.

⁶ Additional specifications of Equations 1 and 2 were estimated in which an interval measure of respondent's education, constructed in the same manner as father's education, was used instead of the set of dummies indicated in Table 2. Increment in R^2 tests (Cohen and Cohen, 1975) suggested that the specifications in Table 2 (hereafter, the "true" equations) for both races explained significantly more variance than the additional equations (hereafter, the "biased" equations): whites, Equation 1, $F = 11.30$, $p < .001$; Equation 2, $F = 9.84$, $p < .001$; blacks, Equation 1, $F = 4.36$, $p < .001$; Equation 2, $F = 3.27$, $p < .01$. These additional equations also evidenced returns to occupational prestige for whites which were statistically significant ($p < .001$), and greater in magnitude than those in Table 2. Analysis of biases in returns to occupational prestige (see fn. 10) suggested 65.32% bias in Equation 1 and 71.01% bias for Equation 2. Comparable figures among blacks are 34.66% and 29.24%, respectively. These findings suggest that ignoring the nonlinear relationship between education and earnings results in upwardly biased estimates of returns to occupational

⁴ Such a finding reflects the disproportionate distribution of blacks across areas. Heavy concentrations of blacks in given areas means that the average black is more likely to live there, and that the average white is not; hence mean level of percent black varies by race.

⁵ Following procedures discussed by Cohen and Cohen (1975), I present significance tests for each set of dummy variables as a group. Increment in R^2 tests were performed to assess whether addition of the (1) education and (2) weeks worked variables resulted in a statistically significant increment in R^2 above a model which omitted these indicators. For both

neither race, which suggests that it is not the investment of migration as such which promotes individual economic advancement. In general, however, the appropriate signs and patterns of statistical significance associated with the terms representing individual investments suggest support for status attainment and human capital models.

Three of the four ecological variables are also significant as predicted. The failure of the unemployment indicator to attain significance may be due to the exclusion of respondents from the sample who reported no earnings in the year prior to the survey. The effect of wage per man hour is positive for both blacks and whites, and as a comparison of the unstandardized coefficients indicates, the returns among blacks exceed those among the whites. The opposing signs of the percentage black coefficients⁷ suggest that while a high proportion of blacks in a labor market hinders black earnings attainment, it may actually enhance the wages of white workers, possibly due to the occupational segregation effect mentioned above. Interestingly, both black and white earnings suffer due to residential segrega-

tion, although the effect is somewhat greater for blacks.⁸

Equation 2 presents an additional specification of the earnings function which includes indicators of past socialization experiences: mental ability, work motivation and father's education. Increment in R^2 tests indicate these variables add to explained variance ($p < .001$) for both blacks and whites. For neither race is the family background indicator, father's education, significantly associated with earnings. Work motivation is significant among whites, but not among blacks, thus suggesting that arguments concerning the importance of this factor in promoting minority economic success may be overstated. Notice, however, that for both races returns to mental ability are positive and statistically significant, and that returns among blacks are greater than among whites. Among both races, with the exception of the education and weeks worked constructs, mental ability is the most important individual-level determi-

prestige, particularly for whites. An alternative explanation also must be considered. Since occupational prestige is measured for job categories which are crude, it is possible that random measurement error prevents this variable from acting as an adequate control when used in the same equation as the educational dummies. However, this latter argument is only plausible to the extent that such measurement error is more severe for whites than for blacks.

⁷ The natural log form of percentage black is used in this analysis following Blalock's (1967) argument concerning the nonlinear relationship between minority concentration and discrimination. However, the logged and nonlogged forms of the variable are highly intercorrelated ($r = .870$ for blacks, $r = .813$ for whites) and alternative specifications of Equations 1 and 2 using the nonlogged form in place of the logged form result in no changes in substantive interpretations. Explained variance is comparable for blacks, and minimally increased for whites using the logged form; there are no major changes in statistical significance or magnitude of individual coefficients, although use of the logged form does result in small increments in returns to wage per man hour among blacks and modest decrements in returns to this variable for whites. Thus use of the unlogged form of this variable would suggest near comparable rates of return to export sector productivity by race, while use of the logged form suggests greater returns to blacks than to whites.

⁸ Statistical explanations for the negative coefficient among whites seem implausible. A reader has suggested that a strong correlation between percent black in and the segregation variable could result in the tipping of these regression coefficients. The zero-order correlations for both races are weak ($r = -.026$ among blacks, $r = .152$ among whites), and additional white specifications which included *either* the segregation *or* the racial competition variable provide no evidence for tipping since the signs reported in Table 2 are retained in the reduced specifications. Inclusion of both indicators increases explained variance for both races in both Equations 1 and 2 at less than the .001 level; we do note, however, that the magnitudes of the percent black and segregations coefficients increase when both are included in the specifications as compared with an equation which just contains either variable. Among blacks the increases run from 13.7 to 15.8%, while among whites the increments are in the 10-11% range for the racial competition variables and the 38.3-39.5% range for the segregation term. While these latter findings are compatible with the argument that there is an incipient tipping effect between these two variables among whites, it would not be appropriate to omit one variable from the model on the basis of these findings. In a further effort to explain the negative segregation term among whites, additional specifications were estimated in which other variables correlated with the segregation index were utilized in place of it; these models failed to yield interpretable results. The statistical significance of the segregation coefficients were assessed with appropriately reduced numbers of cases and the levels of significance reported were retained.

nant of labor earnings. Thus in contrast with Jencks et al. (1972), these findings suggest that mental ability does promote earnings attainment over and above investments in education and weeks worked.

Equation 2 also suggests that the areal labor market characteristics retain explanatory power when additional controls are introduced.⁹ Among whites the coefficients associated with wage per man hour, segregation index and percentage black remain statistically significant and evidence only minimal decrements in the sizes of their slopes. Among blacks, however, while these same coefficients retain statistical significance, we do notice decrements in the slopes of these coefficients which include a 20% reduction in size for the export sector productivity indicator, a 17% reduction for percentage black, and an 11% reduction for the segregation term.¹⁰ These findings suggest that there is some "matching" between labor market and personal characteristics.¹¹ In this case, black workers of higher mental abilities appear to be located in labor markets with more productive export sectors, greater proportions of black residents and greater degrees of residential segregation. Hence when mental ability is controlled,

the effects of these labor market factors are somewhat reduced. Such differential selection/socialization does not appear to be as noticeable among whites. It is important to recognize, however, that the impact of these labor market factors is still substantial among black workers, and nontrivial among whites as well.

These findings suggest that even in the presence of numerous controls for individual investments and personal characteristics, regional labor market characteristics are statistically significant predictors of earnings for blacks and whites.¹² In particular, Thompson's (1965) arguments concerning the importance of export sector productivity in influencing wage levels generally are supported for both races. Arguments by Blalock (1967) and Spilerman and Miller (1976) concerning the economic benefits which accrue to whites and the economic handicaps imposed upon blacks associated with concentrations of blacks in labor markets also receive support. Concerning the findings which suggest that both blacks and whites suffer due to residential segregation, these findings are clearly compatible with previous analyses for blacks (Kain and Persky, 1969; Mooney, 1969; Kain, 1968), though somewhat puzzling for whites. It may be that maintenance of high earnings levels for whites depends upon a given spatial distribution of the races which allows blacks to occupy the "bad" jobs in any neighborhood. If we assume that workers likely to occupy low paying jobs are employed within their neighborhoods of residence, and if residential segregation is high, then some whites will be "forced" to occupy the low paying jobs which in a desegregated neighborhood may go to blacks. Ostensibly if residential segregation were minimal and transportation to

⁹ Additional increment in R^2 tests were computed in order to assess whether the labor market variables explained variance above all of the background and investment variables. Such a strategy reflects a desire to evaluate conservatively the statistical significance of the labor market factors with respect to the background and investment variables. Given the predominance of status attainment models in analyses of inequality, this tack seems a reasonable one, although a "structuralist" could argue that status attainment variables should be tested net of the labor market factors. For both blacks and whites, addition of the labor market variables resulted in increments to explained variance significant at less than the .001 level.

¹⁰ Following Griliches and Mason (1973), I computed these percentages using the formula: $1 - \frac{b_{\text{true}}}{b_{\text{bias}}}$,

where the slopes from Equation 1 are taken as biased and those from Equation 2 as true.

¹¹ Hauser (1974) has argued that forces of social selection may account for the association between a contextual variable and an outcome, due to individuals placing themselves or being placed within contexts for which they are suited. While these findings lend some support to his hypothesis, the partial slopes remain statistically significant; thus the entire association may not be attributed to selection.

¹² It is not possible to indicate the relative importance of individual and structural variables in earnings attainment, partly due to use of dummy variables to represent the education and weeks worked constructs. Also, since the model contains different numbers of individual and structural variables, and since most in each set are statistically significant, comparisons of relative importance of the sets are hindered. In addition, the evidence cited above concerning multicollinearity between personal and structural variables suggests that questions concerning social selection may be more important than those regarding relative importance.

jobs readily available, earnings levels would not be influenced by these factors for either race. In summary, the findings suggest that while whites may lose and blacks may benefit economically if blacks were more proportionately distributed across labor markets, redistribution of the races *within* labor markets may benefit both groups. Both groups of workers may benefit from increments in areal labor market productivity.

We also notice greater levels of explained variance in the black specifications than in the white. Comparable findings have been produced in several other investigations of race and/or sex differences in earnings attainment (Blum, 1972; Treiman and Terrell, 1975; Harrison, 1972; Featherman and Hauser, 1976a, in the more complete specifications), though they have received little comment. These findings are not compatible with the notion that discrimination is manifest in lower returns to key resources for minority as opposed to majority group members. The magnitude of the coefficient of determination reflects in part the magnitudes of the partial slopes, and these slopes are interpreted as the amount of change in the dependent variable associated with a unit change in a given independent variable when the remaining variables are controlled. As we see in the following section, however, under certain circumstances such interpretations are questionable.

ASSESSMENT OF RACIAL DISCRIMINATION

The policy implications of analyses of outcome differences between groups have often been pursued via usage of regression standardization procedures (Duncan, 1969; Coleman et al., 1972b; Blum, 1972; Blinder, 1973; Hall and Kasten, 1973; Suter and Miller, 1973; Siegel, 1965; see Althausen and Wigler, 1972, for a review). Recently, however, Iams and Thornton (1975) have indicated that under certain conditions, estimates derived from several of the previously utilized procedures may be misleading. Their arguments suggest that failure to separate out an interaction component from the remaining terms may lead to erroneous inferences. In this

Table 3. Decomposition of Deflated Earnings for PSOID Blacks and Whites with Deflated Earnings Regressed on Individual Investments and Ecological Variables (Equation 2)

Composition	Components		
	Interaction	Regression Coefficients	Intercepts
\$4,205	-\$1,706	\$4,380	-\$2,352
Computed difference:	\$4,527		
Actual difference:	\$4,528*		

* Discrepancy attributed to accumulated rounding error.

analysis I adopt their procedure and decompose Equation 2 for blacks and whites into several components as follows:

$$\begin{aligned}\bar{Y}_w - \bar{Y}_n = & (b_{ow} - b_{on}) + \sum \bar{X}_{in} (b_{1w} - b_{1n}) \\ & + \sum b_{1n} (\bar{X}_{1w} - \bar{X}_{1n}) \\ & + \sum (\bar{X}_{1w} - \bar{X}_{1n}) (b_{1w} - b_{1n}).^{13}\end{aligned}\quad (1)$$

Such a decomposition will allow us to separate out changes in black/white earnings levels due to (1) the difference in intercepts, (2) the difference in slopes, (3) the difference in levels of resources and (4) an interaction term, interpreted as the effect of jointly changing both means and regression coefficients over the effects of changing them one at a time (Iams and Thornton, 1975:344).

Inferences concerning discrimination will be made on the basis of the decomposition of respective regression coefficients. Of particular interest are those indicators representing features of labor market social and economic organization. It is appropriate to view them as ecological resources, analogous to personal resources, which may facilitate earnings attainment. However, given that we have observed negative signs associated with the social organization indicators, these factors may be operating as mechanisms of racial discrimination, as opposed to resources to facilitate earnings attainment.

Table 3 presents the results of the application of the procedure to Equation 2 while Table 4 presents the full decomposition. Table 3 indicates that both slopes and the composition components are of

¹³ \bar{Y} = mean earnings; w = whites; n = blacks; b = Y intercept; \bar{X}_i = mean of the i^{th} resource; b_i = partial slope of the i^{th} resource.

approximately equal magnitude.¹⁴ This suggests that policy endeavors aimed towards equalizing the aggregate levels of black and white resources relevant to attainment and/or those which contribute to the equal translation of such resource into earnings would both result in the reduction of black-white earnings differences. However, the interaction term is negative: -\$1,706. This finding suggests that *increments* in the *levels* of black resources, for example, probably would result in some *decrements* in the *rates* at which these resources were translated into earnings.

Examination of the full decomposition in Table 4 provides evidence concerning

the potential effectiveness with which particular resources could be manipulated in attempts to promote racial economic equality. Concerning individual investments and personal resources, changes in the levels of resources such as occupational prestige and mental abilities¹⁵ as well as changes in the effectiveness of these two resources would contribute to increments in black earnings. However, we also notice that the interaction components associated with these terms are sizeable and negative; hence it is unlikely that changes in the distribution of the levels of efficacy of mental abilities¹⁶

¹⁴ The negative difference between the two intercepts (\$-2,352) may be due in part to inclusion of terms in the equation which are negative for blacks and positive for whites. When blacks have no access to "resources" which *hinder* their attainment, and whites have no access to resources which *aid* their attainment, the estimated black earnings level, other things equal, will be larger than that for whites. The negative difference also may be due in part to arbitrary zero points used in the scaling of some of the included variables.

¹⁵ Such outcomes may be due to nonlinearity between the independent variables and earnings. If there is a monotonic increasing relationship between mental ability and earnings, then increments in such ability above a given level may be unlikely to be associated with large gains in earnings.

¹⁶ The reader may argue that, following Cain and Watts (1970), it is inappropriate to include variables such as mental abilities or father's education in analyses designed to provide implications for policy. Such variables may not be as directly manipulable by policy as would be respondents' education or job

would result in the aggregate increases which the slopes and composition components would suggest. Concerning the analysis of returns to education, substitution of white for black efficacy of the operation of this resource would produce virtually no increment in blacks' earnings, while changes in the levels of this resource would produce noticeable increments. In addition, however, we see that the interaction component of the educational term is also strongly *positive*; hence changes in the levels and efficacy of educational attainment by race could result in additional increments in earnings due to the positive interaction of these changes. Generally positive contributions to black economic welfare would result from changes in distribution/efficacy of resources such as work motivation and family background as measured by father's education, although the latter effect is small. The bulk of the potential increment in black earnings due to adjustment of the motivation component would be due to changes in the *effectiveness* of the resource; hence the analysis suggests that blacks currently obtain reduced earnings due in part to forms of discrimination which prevent such motivation from yielding the financial returns to blacks which are enjoyed by whites.

Comparable analysis of the areal labor market variables suggests that the largest change in relative black-white economic status would be associated with changes in the distribution of the races across labor markets (percent black 1n). Such change is due to positive contributions from both the composition and efficacy components, although the negative interaction term indicates that the slopes and levels would not change independently of each other. Additional positive change would be

status. However, exclusion of these variables would result in misspecification of the model (Griffin, 1976); hence, inferences concerning the included variables would be erroneous. In addition, while it may be unrealistic to argue that the distribution of *levels* family background variables is directly manipulable by policy, analysis of racial differences in the *efficacy* of resources is an important part of our inference concerning discrimination. Exclusion of these terms from the analysis would prevent assessment concerning whether blacks' "returns" to these resources were equal to those obtained by whites.

forthcoming from equalization of the degree of residential segregation by race; negative changes would result from equalization of export sector productivity, due to blacks' losses in returns to this resource. Hence both residential segregation and racial competition may operate as mechanisms of discrimination against blacks, although alleviation of such discrimination must take into account the interactions outlined above.

These findings serve to temper those produced from the analysis of covariance in that they caution against a too literal interpretation of the regression coefficients, and, by implication, of regression coefficients generally. Particularly, when we observe greater returns to resources among minority than majority groups, we should suspect that such slopes may be due to depressed levels of resources, and thus positive changes in access to resources for minorities may be associated with negative changes in resource effectiveness. Such caution is particularly appropriate in interpreting findings associated with the mental abilities, occupational prestige, percent black 1n and residential segregation terms presented in Table 2.

SUMMARY AND CONCLUSIONS

I have offered arguments in favor of viewing economic status attainment as a function of both individual investments/socialization experiences and characteristics of areal labor markets. Using contextual analysis, I demonstrated that earnings of blacks and whites were positively affected by export sector productivity, negatively affected by residential segregation, and negatively and positively affected by black concentration, respectively; these findings were maintained in the presence of numerous controls for background factors. Policy considerations were explored using a regression standardization which indicated that changes in the distribution/efficacy of resources such as education, occupational prestige, percent black and residential segregation would be associated with improvements in black earnings levels, although estimation of the magnitude of these changes must

consider the interaction of changes in levels and effectiveness of resources. Of course, specific policy directives aimed at promoting racial economic equality must consider additional factors such as costs and feasibility of particular implementations which are beyond the scope of this analysis. We also should recognize that the findings produced in the regression standardization may be particularly sensitive to the specifications of the equations used. While every effort has been made to minimize specification error, equally plausible alternative specifications may yield somewhat distinct findings depending upon the magnitudes of the changes in the relevant slopes for blacks and whites.

Two aspects of the findings from the regression standardization deserve special note. First, it is infeasible to base policy recommendations upon the summary results presented in Table 3 since the findings in Table 4 suggest much variation by variable concerning whether changes in efficacy or levels of resources would be most effective in promoting racial economic equality. Second, it is difficult to advocate specific policy recommendations even on the basis of the analysis in Table 4 because important questions remain unaddressed. For example, given that increments in black resource levels may be associated with decrements in resource efficacy, should resource levels be equalized or not? If resource levels are equalized and that results in decrements in blacks' resource efficacy, there may still be major gains in black earnings due to their increased levels of available resources. Such an hypothesis is clearly speculative since it rests solely upon these correlational findings. However, given that younger cohorts evidence greater equality in access to personal resources than this one (Featherman and Hauser, 1976b), we may expect that greater racial equality in access to personal resources may be accompanied by actual decreases in returns to these factors, an important question for future research. We also may expect that under these conditions variations in structural resources will produce even stronger structural effects on earnings for these younger groups than for the cohort used in

this analysis. Such reasoning assumes that the racial distribution of structural resources remains fixed, an outcome which is far from certain. We also wonder how resource efficacy itself can be changed. It is possible that general programs aimed at reducing discrimination in employment—e.g., not requiring blacks to have superior qualifications to whites to obtain a given job—would result in equal observed returns to personal resources, but it is difficult to extend such arguments to apply to institutional resources.

Nonetheless, the analysis has provided clear evidence for the importance of regional labor market characteristics in the earnings attainment process for both blacks and whites. Theoretical arguments by Thompson (1965), Kain (1968) and his colleagues, Blalock (1967) and Spilerman and Miller (1976) have been supported. Finally, it is worth emphasizing again that the contextual models tested have permitted evaluation of structural explanations of inequality while simultaneously controlling for individual-level determinants of earnings. Hence, *both* perspectives have been subjected to (and withstood) a more conservative test than previously has been made. Carefully utilized, contextual analysis may be a valuable aid in the synthesis of theoretically related traditions which have not been effectively empirically integrated due to differing measurement strategies. Attention here has been focused upon a synthesis of background/investment and areal labor market explanations of inequality. Additional research is planned where occupational and industrial labor market characteristics will be similarly integrated with status attainment/human capital models. Areas of sociology in addition to that of status attainment and inequality, however, which also have evolved using both individual- and aggregate-level analyses of related phenomenae may find these arguments useful as well.

POVERTY AND INFANT MORTALITY IN THE UNITED STATES*

STEVEN L. GORTMAKER

Harvard University

American Sociological Review 1979, Vol. 44 (April):280-297

This paper examines the theoretical and empirical relationship of income poverty to infant mortality differentials in the contemporary United States. Using national data gathered in 1964-65, this study estimates the relative impact of a variety of biological, social, and economic factors upon the risk of infant death. Methods for the analysis of multidimensional contingency tables permit the combination of birth and death data, and coefficient estimates from these models provide estimates of the relative risks of infant death observed in various subpopulations. Within the white population of legitimate births in 1964-65, coefficient estimates indicate that poverty is associated with relative risks of neonatal and postneonatal mortality 1.5 times greater than that experienced by infants not born in poverty, independent of a variety of maternal and familial characteristics and the birth weight of the infant. Hospital care during the neonatal period, however, appears to attenuate this increased risk for some high risk infants. The estimated direct effects of poverty upon infant mortality are larger than the effects of poverty mediated by the birth weight of the infant. The persistence of poverty and the continuing unequal distribution of health care resources to pregnant women and young mothers in the United States imply the reproduction of these differentials to the present day. Increasing access to health services and increased help to families through income supports and employment programs are indicated as possible policy actions to reduce these differentials.

1. INTRODUCTION

Social scientists have documented extensively inverse relationships between the socioeconomic status of individuals and their risk of death in the industrialized countries of the world; individuals with less income, less education, and of lower

occupational status tend to experience higher rates of mortality than persons of higher status. Furthermore, in spite of substantial improvements in standards of living, educational attainment, and access to medical care during recent decades, these differentials persist to the present day in the industrialized nations (Benjamin, 1965; Antonovsky, 1967; Kitagawa and Hauser, 1973; Kitagawa, 1977). Such differential mortality can be conceptualized as one possible consequence of the stratification process imposed upon and negotiated by individuals during their lifetimes; mortality differences thus constitute an important measure of the quality of life associated with different statuses.

Stratification differentials can cause differential mortality, as in the case of certain occupationally related diseases. Many deaths, however, are the consequence of behaviors such as smoking and auto accidents (Fuchs, 1975) which are less directly related to socioeconomic status. In addition, some individuals become ill and lower their income status before death, resulting in a reversed casual relationship (Kitagawa and Hauser, 1973). Thus, the association of adult mortality to socioeconomic status is difficult to specify in general.

During the preparation of this work the author was supported by the National Institute of General Medical Sciences Training Program in Methodology and Statistics Grant 5-T01-GM011526-08, by funds granted to the Institute for Research on Poverty at the University of Wisconsin-Madison, by the Office of Economic Opportunity pursuant to the Economic Opportunity Act of 1964, and by a Center for Population Research Grant No. HD05876, from the Center for Population Research of the National Institute of Child Health and Human Development to the Center for Demography and Ecology at University of Wisconsin-Madison. I am indebted to Hal H. Winsborough for constant encouragement and many instructive discussions and would like to thank Robert M. Hauser and David Mechanic for helpful comments on an earlier draft. The comments of two anonymous reviewers are gratefully acknowledged. The data were obtained from the National Center for Health Statistics. The opinions expressed are those of the author and should not be attributed to the institutions or individuals named above.

The present analysis examines infant mortality differentials in the contemporary United States, and asks the question: Is poverty hazardous to an infant's health? The extreme dependence of the newborn upon others makes infant mortality a sensitive measure of the quality of life associated with different socioeconomic environments. Furthermore, infants exercise no responsibility for their environment and health status, and thus an infant's own motivations and actions have little impact upon its chances for survival; most influences should come from its parents and the surrounding environment.

Differentials in infant mortality rates between population groups have been a topic of interest to social scientists for a long time. In the latter half of the nineteenth century, for example, Marx (1867:397-8) described in detail the differentials in infant mortality existing across registration districts in England; they ranged from a low of 70 per 1,000 to a high of 250 per 1,000 in the most heavily industrialized areas of the country. These differentials were in large part a result of the terrible conditions under which these exploited working-class populations lived. Income poverty, inadequate sanitation, poor health care, inadequate nutrition, and mothers who were forced to work because of their poverty, and thus neglected their children were all too common circumstances into which children were born.

Although such extremely high absolute levels of infant mortality are no longer found in the industrialized countries of the world, the persistence of class differentials within these countries has been documented. Research in Great Britain, for example, indicates that infant mortality differentials by occupation of father persisted throughout the years 1911-1949, despite tremendous increases in the general standard of living and in the quantity and quality of medical care made available under the National Health Service (Morris and Heady, 1955:344).

Differentials in infant mortality in the United States have been linked to income poverty of the parents since the beginning of this century (Children's Bureau, 1921)

and national data from 1964-66 indicate the contemporary persistence of this relationship: in 1964-66 white infants born to parents earning less than \$3,000 per year experienced a death rate of 27.3 per 1,000, while white infants born to parents earning \$5,000 or more per year experienced a death rate of 18.6 per 1,000 (National Center for Health Statistics, 1972).

These differentials take on added significance when it is realized that death rates during the first year of life in the United States are exceeded only by death rates of those aged 65 and older (U.S. Department of Commerce, 1974). Old age and infancy are the times of greatest risk to human life, and thus the magnitude of these observed differentials is considerable. However, a consciousness of the meaning of these different rates may not be widespread throughout a population—only one in 50 parents of new infants experience an infant death in a given year. A better understanding of the magnitude of these differentials is gained by applying the mortality rate experienced by infants born to parents earning \$5,000 or more per year to infants born to parents earning less than \$3,000. If the entire infant population in the United States could have experienced the wealthier force of mortality, approximately 4,000 more infants would have survived each year.

The mere existence of differentials by income, however, does not constitute a satisfactory explanation of these differences. There are a variety of other factors related to infant mortality which also may be related to income (Shapiro et al., 1968; Institute of Medicine, 1973; Mechanic, 1968) and thus we need to control for such factors within the context of a theory if convincing tests of relationships between income poverty and infant death are to be made.

Poverty, for example, occurs often among young families (Lampman, 1971:72), and infants born to young mothers experience higher risks of infant mortality than infants born to mothers in their middle and late twenties (Shapiro et al., 1968). Thus, any assessment of the relationship between poverty and infant mortality must include correlated factors such as age of mother in the analysis so

that these other possible explanations can be tested and controlled.

2. METHODOLOGICAL APPROACH

The present study estimates multivariate structural equations which predict infant mortality and other intervening variables—such as birth weight—in the infant mortality process. The data consist of nationwide random samples of births and infant deaths (defined as occurring during the first year after birth) in 1964–65 in the United States (National Center for Health Statistics, 1972). Three aspects of the present approach are particularly noteworthy. First, although systematic experimental trials (including randomized assignment to treatment) offer the most desirable evidence for imputing causality, a variety of problems render them inappropriate for the research reported here. Ethical problems with the manipulation of life chances, as well as cost considerations in the alteration of stratification characteristics of a population combine to make the present observational approach quite attractive. By statistically controlling for a variety of factors simultaneously, the present research should offer some reasonable estimates of effects. Furthermore, quite a large amount of natural variability exists within the United States population; this fact provides the present research with considerable numbers of situations to study. In particular, it offers the opportunity to look at the extremes of the stratification system, for, as will be discussed later, it is under situations such as extreme poverty that substantial effects upon infant mortality are expected.

Second, the data is somewhat unique in that it comes from national random samples of infant births and deaths (National Center for Health Statistics, 1972). Most previous research looking at the relationship of socioeconomic status to infant mortality in the United States has depended upon local samples from areas such as New York City (Institute of Medicine, 1973), upper New York state (Chase, 1964), Baltimore (Shah and Abbey, 1971), and Wisconsin (Slesinger and Travis, 1975). No problems of generaliz-

ing to the total United States population are encountered with the present data.

Finally, the present work utilizes relatively recently developed log-linear models for the analysis of multidimensional contingency tables. These methods permit the combination of samples of births and infant deaths, and allow for the multivariate analysis of relative risks. Illustrative diagrams display variables and their relationships (Goodman, 1973a) and serve as useful guides to the theory being tested in much the same way that path diagrams have proven helpful in the conceptualization of social phenomena (Duncan, 1966). The usefulness of this approach lies in the researcher's ability to display casual assumptions concisely, and to explicitly test theories based upon these assumptions. Through the estimation of structural equations, one gains insight into the relative magnitudes of effects operating, and obtains an overview of the process under investigation.

The data were collected between 1964 and 1965 as part of the National Center for Health Statistics (NCHS) National Natality and National Infant Mortality Surveys (NNS and NIMS). These surveys were designed to obtain information not normally found on birth and death certificates—in particular, questions about the socioeconomic characteristics of the infants' parents were asked. Similar questionnaires were used for both the birth and infant death surveys; only deaths to legitimate infants were included in the study.

Information on respondents was obtained from a variety of sources: birth certificates (NNS), death certificates (NIMS), hospital records (NIMS), as well as from the questionnaires themselves (both NNS and NIMS). The questionnaires usually were completed by the mother, but in rare instances by other family members (NCHS, 1972:2). The questionnaires initially were mailed to respondents; follow-up procedures were used, including remailings as well as personal interviews if no response occurred within two to three weeks. "For the 2,160 legitimate infant deaths in the 1964–1966 NIMS, the response rate was 88%. For

the 10,395 legitimate births in the 1964-1966 NNS, the response rate was 89%" (NCHS, 1972:46). The statistics in the present research are based upon poststratified responses and thus should be more representative of the population of births and infant deaths than would be expected with a random sample alone (NCHS, 1972:50).

3. STRATIFICATION AND INFANT DEATH IN THE UNITED STATES

A large variety of socioeconomic variables has been related to differentials in infant mortality. These include: parental income (Children's Bureau, 1921; Anderson, 1958; Willie, 1959; Willie and Rothney, 1962; Stockwell, 1962; Fuchs, 1974; NCHS, 1972); education of mother (NCHS, 1972; Institute of Medicine, 1973; Slesinger and Travis, 1975); education of father (NCHS, 1972); occupation of father (Morris and Heady, 1955; Chase, 1964); and racial-ethnic identity (Shapiro et al., 1968). The present analysis focusses upon the achieved statuses above, particularly income, although further work upon racial differentials is being prepared (Gortmaker, 1977b).

An important distinction often made in the analysis of infant death defines two components of infant mortality: neonatal mortality, or deaths to live-born infants which occur during the first four weeks of life, and postneonatal mortality, or deaths which occur during the remainder of the first year of life. Neonatal and postneonatal death rates are defined as the number of neonatal or postneonatal deaths per 1,000 live births. By definition, in any given year, the neonatal and postneonatal mortality rates sum to the infant mortality rate for that year.

One important characteristic of the distinction just made is that different causes of death predominate in the neonatal and postneonatal periods. Neonatal mortality tends to be dominated by death classifications such as immaturity of the infant, postnatal asphyxia and atelectasis, birth injuries, and congenital malformations—in general, causes of death were the "influence of conditions

present before birth or that occur during the birth predominate" (Shapiro et al., 1968:27). Alternatively, during the "postneonatal period, the infectious diseases, particularly pneumonia and influenza, dominate as causes of death. Also, accidents begin to assume a major role in mortality" (Shapiro et al., 1968:27).

These two components of infant mortality are related differentially to environmental factors which influence the health of the newborn. In particular, deaths to infants with congenital malformations often are unrelated to the environmental conditions under which an infant develops, with the exception of certain teratogenic agents such as thalidomide (Gruenwald, 1974). Deaths due to the immaturity of the infant similarly have been described as being related in little known ways to the environment of the developing fetus (Morris and Heady, 1955; Shapiro et al., 1968:92). Many deaths due to infectious diseases such as pneumonia and influenza, on the other hand, certainly could be prevented through improved medical and home care (Department of Health and Social Security, 1970) and thus should be influenced strongly by environmental factors. These rough distinctions imply that socioeconomic differentials in infant mortality are very likely largest in the postneonatal period, although there also exists potential for reduction of deaths due to infection by prophylactic health measures during the neonatal period (Vaughan and McKay, 1975:322).

Studies of the relationships between socioeconomic status and infant mortality which focus upon this distinction have come to two general conclusions. First, a tremendous change has taken place in the last half-century in the distribution of deaths into these two categories. In 1918, approximately 44% of all infant deaths occurred during the neonatal period, and thus 56% occurred during the postneonatal period (National Office of Vital Statistics, 1920). In contrast, the 1974 distribution indicates that 77% of all infant deaths occurred during the neonatal period, and only 23% occurred during the postneonatal period (National Office of

Vital Statistics, 1975). This decline in the relative size of the postneonatal component has been interpreted to mean that the importance of socioeconomic variables in the infant mortality process has declined over the last 60 years (Morris and Heady, 1955; Willie, 1959; Stockwell, 1962).

Secondly, these studies point to the significance of income in the determination of relative risks (Anderson, 1958; Willie, 1959; Willie and Rothney, 1962; Stockwell, 1962), although the rather small contemporary relationships found have led these authors to emphasize the changing nature of infant mortality, and thus to downplay the current relationships between income and infant death. Because these studies used small samples and highly aggregated units of analysis, however, this emphasis may seem questionable. Recent national data (NCHS, 1972) indicates quite significant differentials in infant mortality rates by income; unfortunately, no distinction is made in this analysis between neonatal and postneonatal death and few controls for other variables are made. Other recent results based upon more restricted samples, but utilizing sophisticated techniques of analysis, indicate significant relationships between the socioeconomic status of census tracts and the increased risk of postneonatal mortality (Shah and Abbey, 1971), and a significant relationship between education of the mother and infant mortality (Slesinger and Travis, 1975). No income measures are included in these studies.

Previous research thus has demonstrated the existence of significant differentials in the risk of infant death by a

variety of indices of socioeconomic status, within a variety of locales, and while statistically controlling for a variety of variables. Yet, a precise explication of the role of poverty in the infant mortality process in the United States remains to be accomplished. The present research offers some initial estimates of the relationship of poverty to infant mortality through estimation of multivariate structural equations.

4. A CONCEPTUAL MODEL: THE EFFECTS OF POVERTY UPON INFANT DEATH

A significant orientation of the present research is a focus upon extreme income poverty as a determinant of infant death, as opposed to the specification of a linear relationship between family income and differentials in infant mortality. As Mechanic (1968:246) suggests:

—the relationship may hold only when deprived social and cultural groups are involved, so that we might expect a curve characterizing the relationship to reach a plateau at a level of income which might be thought of as relatively low.

The notion of such a critical income level was introduced by Anderson (1958), and research by Willie and Rothney (1962), as well as more recent national data (NCHS, 1972) support this conceptualization.

The definition of poverty used in the present analysis is based upon guidelines published by the Community Services Administration which take into account total family income, family size, and consumer prices as charted by the Consumer Price Index (Community Services Administration, 1975). (See Appendix.) Table 1 presents estimates of both

Table 1. Estimated Neonatal and Postneonatal Mortality Rates by Poverty Status of Family for White, Legitimate Infants, 1964-65 in the United States^a

Poverty Status of Family	Births	Neonatal Deaths	Postneonatal Deaths	Neonatal Rate**	Postneonatal Rate**
Parents Income below Extreme Poverty*	907	188	85	22.8 (1.2)	10.3 (1.0)
Parents Income above Extreme Poverty*	5,278	690	218	14.4 (.7)	4.5 (.3)

* See the Appendix for discussion of extreme poverty guidelines.

** Both neonatal and postneonatal rates are expressed as deaths per 1,000 live births.

^a Note: births must be multiplied by 1,000 and deaths by 110 to obtain population estimates. Approximate standard errors given in parentheses. (Standard errors obtained from NCHS, 1972:53.)

neonatal and postneonatal mortality rates by poverty status of a family in 1964-65.

The human infant is remarkably dependent upon others for survival at birth, and newborn humans are thus exceedingly susceptible to negative influences upon their health. The fact of poverty can present a variety of hazards to the newborn and can impose constraints upon many areas of parental activity in defense of their offspring. These hazards and constraints can emerge in the form of inferior housing, poor sanitary facilities at home, lack of adequate food and clothing, inadequate hospital or postnatal medical care, lack of transportation facilities—meaning difficulty in obtaining needed services. Finally, those in poverty are often vulnerable to the experience of stressful situations. All of these factors can have damaging effects upon the health of the newborn. Poor housing, for example, has been implicated in high rates of death due to infectious diseases during the two to eleven months after birth in England (Department of Health and Social Security, 1970) and preventable infections are also prevalent in the neonatal period (Vaughan and McKay, 1975: 322).

One useful distinction concerning the effects of poverty upon infant mortality separates the effects of poverty described above—those which impinge directly upon the newborn—from the consequences of poverty which may hinder the development of the fetus, and hence which are mediated quite literally by the mother during the prenatal period. The most studied indicator of the development of the fetus is birth weight: although only 7% of all births in the present study are of low birth weight (less than 2,500 gm), 61% of all infant deaths occur to this 7%. Birth weight is thus usually described as the intervening variable which best predicts infant mortality.

Furthermore, a substantial number of characteristics of the mother and her behaviors has been linked to an increased risk of low birth weight. Both "natural experiments" with famines during World War II (Smith, 1947; Antonov, 1947) and a more recent experiment in Guatemala (Habicht et al., 1974) highlight the impact of inadequate nutrition of mothers upon

subsequent birth weight of the infant. Low maternal weight (O'Sullivan et al., 1965; Rush et al., 1972), maternal smoking (Fielding and Yankauer, 1978a), consumption of alcohol (Fielding and Yankauer, 1978b), and lack of prenatal care (Institute of Medicine, 1973; Gortmaker, 1979) are other factors related to the increased risk of low birth weight. The extent to which poverty is related to infant death both independently of birth weight, and indirectly via birth weight, thus provides two different explanations for the effects of poverty upon infant mortality. Strategies to reduce the impact of poverty upon birth weight should be aimed at helping the mother during the prenatal period; strategies directed toward infant deaths which are related to poverty independently of birth weight, in contrast, should be aimed at helping the mother and infant during and after birth.

Another important distinction concerns the effects of poverty—and other aspects of stratification—which may influence infant death indirectly through the health care received by mother and infant, and those effects of poverty which influence infant mortality independently of the delivery of health services. A variety of health practices have been related to the risk of infant death. For example, prenatal care has been related to increased risk of low birth weight (Institute of Medicine, 1973; Gortmaker, 1979); neonatal intensive care has been linked to decreased risk of death due to small size and immaturity of the newborn (Institute of Medicine, 1973); and postneonatal deaths may be averted through appropriate physician and hospital practice (Department of Health and Social Security, 1970: 20). Three indicators in the present data set allow for some control over the indirect influences of poverty via health care: Birth weight already has been mentioned as one factor sensitive to care received during the prenatal period. Whether or not the baby was delivered in a hospital serves as one extreme indicator of lack of medical care. Finally, whether or not health insurance for physician and hospital care is possessed by parents serves as a rough indicator of the availability of medical care. These variables must be recognized as

only crude indicators of the receipt of health services by mother and child, and thus the impact of health care may be underestimated in our analyses.

A variety of other factors have been associated with infant mortality differentials, and are included in the present analysis. Educational attainment of the mother and father, for example, serves to indicate a variety of nonfinancial characteristics of the family, such as knowledge of health practices, or life-style differences which may influence the care of a developing child (Slesinger, 1973; Benjamin, 1965:48-9).

Age of the mother also has been associated with differential chances for infant survival. Certain birth defects, such as chromosomal abnormalities, occur more often to older women (Apgar, 1970). Young age of the mother is associated with increased risk of infant death, although recent research indicates that the effect of a young woman's age upon infant mortality may in fact be due to the relatively lighter weight of young mothers (O'Sullivan et al., 1965; Rush et al., 1972) or to a lack of prenatal care (Gortmaker, 1979).

Increasing risks of death also are reported for increasing birth orders (Shapiro et al., 1968:60-1). One interpretation of this relationship is that increasing family size leads to increased chance of the spread of infectious disease, as well as to increased strain on parental care, and thus to increased postneonatal mortality (Benjamin, 1965:46).

Mothers who had a previous history of pregnancy loss or who experienced a previous infant death exhibit higher than average rates of infant death in their current pregnancy (NCHS, 1973). A possible explanation is the hypothesis that "certain women may be reproductively more efficient, because an undue number of pregnancy losses appear to be concentrated in a relatively small group of women, and the type of loss tends to be repeated" (Institute of Medicine, 1973:118-9). This variable will be controlled in the analyses that follow in order to rule out the hypothesis that observed relationships may be due to such a biological mechanism. Finally, the present analysis is restricted to the popu-

lation of white, legitimate infants in the United States. Other analyses have been prepared, however, which examine differentials in infant mortality by race and legitimacy status (Gortmaker, 1977a; 1977b).

5. ANALYTIC METHODS

Discrete multivariate logistic, or modified multiple regression models, in large part developed and expositied by Yvonne M. M. Bishop (Bishop and Mosteller, 1969; Bishop et al., 1975) and Leo A. Goodman (Goodman, 1972; 1973a; 1973b) are applied to the present data. Quantitative models of the following form thus are used as a means of specifying and estimating relationships between variables of interest:

$$E(\text{death rate}_{ij\dots n}) = \gamma\gamma_i^A\gamma_j^B\dots\gamma_n^N. \quad (1)$$

This formula states that the expected death rate for cell $ij\dots n$ of a N dimensional cross-classification table can be written as a product of γ 's. Furthermore, the model specifies that $\Pi\gamma_k^K = 1.0$, for $K = A, B, \dots, N$. The i, j, \dots, n indices refer to levels of dimensions A, B, \dots, N . Taking the natural logarithms of both sides of formula (1) results in the equivalent log-linear expression:

$$\lg E(\text{death rate}_{ij\dots n}) = B + B_i^A + B_j^B + \dots + B_n^N, \quad (2)$$

where $B = \lg\gamma$, $B_i^A = \lg\gamma_i^A$, $B_j^B = \lg\gamma_j^B$, \dots , $B_n^N = \lg\gamma_n^N$. Furthermore, this reparameterization specifies that $\sum_k B_k^K = 0.0$.

Higher order interaction terms also can be added to equations (1) and (2).

Maximum likelihood estimates of the γ 's (or equivalently, of the B 's) are obtained under a variety of sampling schemes using programs such as ECTA.¹ This fact is fortuitous for the present research; although the data consist of probability samples of one out of every 1,000 births and one out of every 110 infant deaths, these samples do not have to be

¹ ECTA, a program to calculate log-linear fits for hierarchical models for contingency tables, is available from Professor Leo A. Goodman, Department of Statistics, University of Chicago.

weighted differentially to obtain maximum likelihood estimates of the B_n^N (or γ_n^N parameters) (Bishop et al., 1975). The $B = \lg y$ parameter estimates are affected, but these are of little substantive interest. No corrections for degrees of freedom are thus required for statistical tests. Statistics based upon these maximum likelihood estimates are distributed according to the χ^2 distribution. The flexibility of this log-linear model to accept such data is one reason to favor this approach over a regression approach. In addition, other problems such as heteroscedasticity and out-of-range estimates (Goldberger, 1964; Nerlove and Press, 1973) are avoided.

The effect parameters estimated under a given model are interpreted in a variety of ways. The relative sizes of the effect parameters indicate the relative influence upon the dependent variable of the different independent variables in the model, or their interactions. In addition, ratios of the estimated γ coefficients can be interpreted in terms of relative risks (MacMahon et al., 1960:229). An example should make this property of the model clear. For simplicity, let the variable A have two categories: $\gamma_1^A =$ being in income poverty, $\gamma_2^A =$ not being in income poverty. Furthermore, let the sample estimates for these coefficients equal $\hat{\gamma}_1^A = 1.2$ and $\hat{\gamma}_2^A = \frac{1}{1.2}$.

The effect of being in income poverty upon the expected death rate is to multiply the product $\hat{P} = \hat{\gamma}_1^A \dots \hat{\gamma}_n^A$ by 1.2, while the effect of not being in income poverty is to multiply this product by $1/1.2$ (with the effects of all other factors held constant). Thus, the relative effect of $\hat{\gamma}_1^A$ vs. $\hat{\gamma}_2^A$ is to increase the expected death rate under the given model by a factor of $(1.2)^2 = 1.44$. Taking condition 2 as a base (not being in poverty), one can say that the effect of the poverty condition, net of other variables in the model, is to increase the death rate 44%. Similarly, one can obtain a comparable figure from the log-linear form (2).

6. SPECIFICATION AND ESTIMATION OF EQUATIONS

Two varieties of infant death are specified: both neonatal and postneonatal

mortality.² Parents are classified as either in or out of poverty; application of the extreme poverty guidelines presented in the Appendix results in approximately 15% of births to two-parent white families in 1964-65 occurring in poverty.

Education of mother and education of father are dichotomies which classify them as having less than nine years of completed education. Age of mother is defined by four categories: less than 20, 20-24, 25-34, and 35+. Birth order of the child likewise is divided into four categories: first, second, third, and fourth or higher order birth. Whether or not the mother experienced a previous loss (fetal death or miscarriage) or an infant death is represented by a variable termed *pregnancy experience*.

Two variables relate directly to the health care experience of the mother: these concern whether the parents do not possess health insurance for physician and hospital care, as well as whether or not the baby is delivered in a hospital.

Finally, birth weight of the infant is coded as either less than or greater than 2,500 grams, the commonly accepted definition of low birth weight. The use of a dichotomous measure, rather than a simple linear one, is indicated by the fact that infant death rates are related to birth weight in a nonlinear fashion. For infants weighing less than 2,500 gm at birth, death rates are quite high. For those infants weighing less than 2,500 gm, however, there is substantially less variation in the risk of death. Birth weight is utilized as an indicator of fetal development, rather than other measures such as gestation length, because research has indicated that birth

² The samples are of births and deaths, and thus the dependent variables are expected death rates for a particular cell of a cross-classification table. The numerators are for these expected numbers of neonatal and postneonatal deaths. The models assume that the exposed population is in each case the same—the expected total number of live births in that particular cell. Strictly speaking, the exposed population for the postneonatal period would be better approximated by the live births minus all neonatal deaths. Such a correction, however, amounts to a change of only approximately 120 (out of 7,000) exposed infants. For simplicity, this imprecision in the estimation procedure is ignored.

weight is more influenced by environmental factors (Gruenwald, 1974; Gruenwald et al., 1967), and is also more predictive of subsequent infant problems than is a short gestation (Neligan et al., 1976).

The infant mortality process is conceptualized as a causally ordered sequence; this leads to the specification of a variety of dependent variables. Some of these are considered the outcome variables of greatest interest, such as neonatal mortality and postneonatal mortality, while others, such as birth weight of the infant, are considered intervening variables. Operationalizing this view of the infant mortality process in terms of the variables defined above results in a set of recursive relationships which are illustrated in Figure 1.

The mother's prior pregnancy experience thus is seen as determined in part by social and demographic characteristics of her family and herself, while lack of possession of insurance for physician and hospital care is conceptualized as dependent upon these family background factors, as well as upon the mother's prior reproductive experience. Birth weight, in turn, is related to all factors which characterize the mother's and family's situation prior to birth. Neonatal mortality (and postneonatal mortality) occur during the year following birth, and thus constitute the end points of the process.

Each of the dependent variables noted above contains two categories. Hence, each of the relationships described was translated into an equation of the log-linear form indicated in equation (2) above. The dependent variable in all cases is the log of the expected odds of being in one category of the dependent variable vs. being in the other category, conditional upon given values of the independent variables. In the case of neonatal and postneonatal mortality, the dependent variables are the logarithms of expected death rates, since the two categories correspond to deaths and births. For all other equations, no one has yet died, and thus the sample consists only of births.

Maximum likelihood estimates for these equations are presented in Figure 1 and Table 2. Figure 1 only includes coeffi-

cients which test significantly different from zero at $\alpha = .05$.³

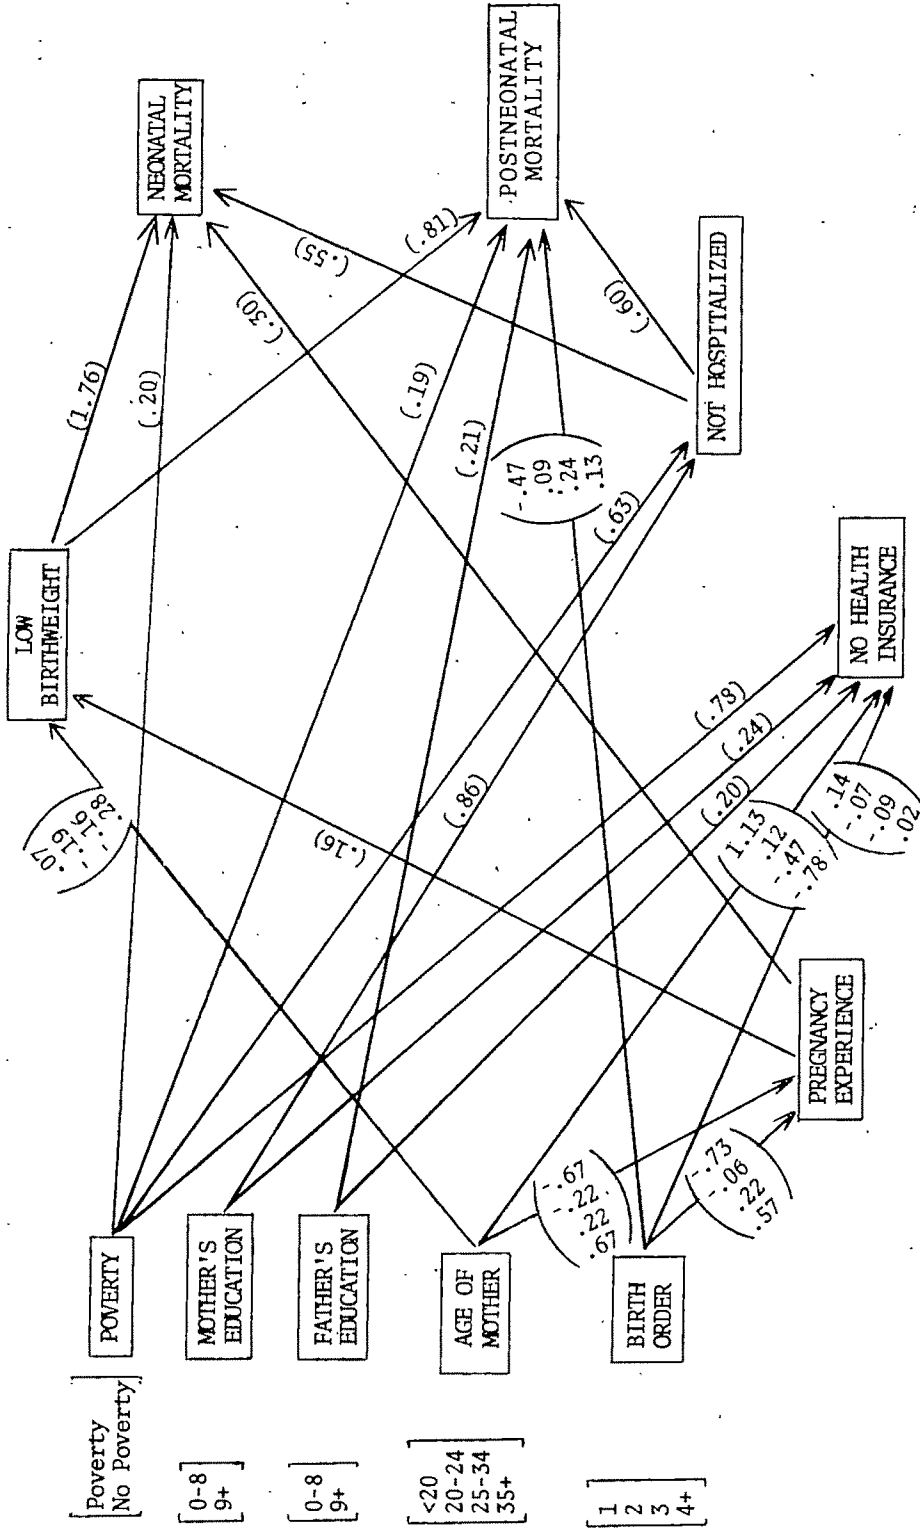

The overall fit a regression equation is characterized by an R^2 statistic. Researchers analyzing infant mortality with regression models have noted with disdain the low R^2 's produced, the inference being that a low R^2 means the model has little explanatory power (see e.g., Institute of Medicine, 1973: 63-4). Regression equations predicting neonatal mortality from the present data set, for example, have R^2 's of approximately .44. Postneonatal mortality is more difficult to predict with an R^2 of approximately .06. Goodman (1972) has developed an R^2 statistic for use with the discrete logistic model; this R^2 statistic for the equation predicting neonatal death is approximately .75; the postneonatal equation produces a statistic of .20.

Given that most of the explained variance in the equation predicting neonatal death is accounted for by the birth weight variable, these R^2 statistics thus indicate a moderate to poor amount of predictive precision, and reaffirm the difficulty of predicting precisely who will die given only background characteristics of infants. The analyses that follow will not dwell upon this lack of precision, but rather will focus upon identifying factors related to the greatest changes in the probability of death; our emphasis is thus upon relative risk.

7. CAUSAL ANTECEDENTS OF INFANT DEATH

The estimates in Figure 1 and Table 2 indicate that income poverty, as defined here, is a major antecedent of lack of health insurance among the white population of infant's parents. When other factors in the model are controlled for, poverty status leads to a five-fold increase ($e^{2.78} = 5.0$) in the chances of a family not possessing health insurance over those families not in poverty. Likewise, poverty status of the family leads to a

^a N = 6,185 births, and 878 neonatal and 303 postneonatal deaths. All effects (or set of effects) shown are significantly different from zero at $\alpha = .05$.
Figure 1. Coefficient Estimates of Factors Affecting Neonatal and Postneonatal Mortality among White, Legitimate Infants in the United States in 1964-1965^a

tripling of the odds of the infant not being born in a hospital over families not in poverty.

These findings support the well-accepted notion that access to health care in the United States (in 1964-65) is structured significantly by a lack of monetary resources. It is also of interest to note that the largest effects upon possession of health insurance are those associated with young age of the mother. These estimates should be tempered, however, with knowledge of the number of individuals implicated in these associations. Only an estimated 1.6% of all births during the study period, for example, did not occur in a hospital.

No statistically significant direct effects of poverty or education of parents upon birth weight are found. The possession of health insurance, however, exhibits an effect significant at the .10 level. The magnitude of this effect indicates that lack of insurance for physician and hospital care leads to a 22% increase in the odds of a mother having a low birth-weight infant. This finding supports a theory that health care—and in particular, prenatal care—may be instrumental in lowering rates of low birth weight, as the positive effect of prenatal care in reducing the risk of low birth weight has been indicated in other studies (Institute of Medicine, 1973; Gortmaker, 1979).

Coefficients similar in sign, but smaller in magnitude, likewise characterize the partial relationships of poverty and education of parents to birth weight; the statistical insignificance of these effects, however, precludes discussion of their role in structuring the risk of low birth weight. In contrast, the differentials in risk associated with age of the mother and the mother's previous pregnancy experience are large. Both of these latter findings are consistent with previous research (O'Sullivan et al., 1965) although, as noted earlier, the observed relationship between young age of mother and low birth weight may reflect a relationship between low prepregnant weight of the mother and low birth weight of the infant, and this relationship in turn also may reflect a lack of prenatal care.

8. DETERMINANTS OF NEONATAL AND POSTNEONATAL DEATH

The largest estimated effects upon both neonatal and postneonatal mortality, as expected, are those associated with low birth weight of the newborn infant. Only a small indirect relationship between poverty and low birth weight, however, was detected. In contrast, significant direct relationships between income poverty and both neonatal and postneonatal mortality are indicated. The magnitudes of the estimated coefficients indicate that being born into income poverty vs. not being born into income poverty increases an infant's risk of death by almost 50%—both in the neonatal and postneonatal periods. These results imply that the largest effects of poverty upon infant death are related to the environment of the newborn, and to a lesser extent to the prenatal environment.

Nonhospitalization of the infant at the time of birth is quite strongly associated with both neonatal and postneonatal death, as indicated in Figure 1. Since nonhospitalization exhibits equally large effects upon both neonatal and postneonatal death, however, more than the mere fact of nonhospitalization is probably being measured. This variable might be indicative of a general lack of any medical care. Although the effects associated with nonhospitalization are large and statistically significant, relatively few deaths will be associated with poverty via this route because of the small number of births not delivered in a hospital. Although the number of deaths involved would thus have little impact upon national rates, this finding does illustrate one extreme effect of poverty as it relates to infant death.

Low education of the father is another factor significantly associated with an increased risk of postneonatal death, indicating the role that nonfinancial characteristics of stratification can assume. In addition, the estimated effects of a large family size upon postneonatal death are larger than any of the estimated effects of poverty or education. This fact indicates the significant impact that reduced family size might have upon infant mortality.

In summary, our analysis of the structural equations predicting infant death supports many results indicated in other studies of infant mortality in the United States. One somewhat unexpected, but important finding concerns the extent to which poverty is related to infant mortality indirectly via low birth weight, and the extent to which poverty is related to infant mortality independently of the infant's birth weight. The largest effects of poverty estimated were direct, and these indicate the particular vulnerability of the newborn to a life of poverty.

9. INTERACTIONS AND MISSPECIFICATIONS

Thus far, it implicitly has been assumed that the estimated effects of poverty upon infant death are the same across all categories of the other variables. Tests of this assumption were constructed: first, all nonsignificant main effects were dropped from the equations predicting neonatal and postneonatal mortality. Second, all second-order interactions (two-way) which tested significantly different from zero were added to the main effects model. The significance tests for these interactions are given in Tables 3 and 4.

Finally, a best fitting equation was estimated by dropping those interactions which did not test significantly different from zero. The coefficient estimates for these equations are given at the bottom of Tables 3 and 4.

The estimated interactions in the equation predicting neonatal mortality indicate that a model strictly multiplicative in the probabilities does not quite fit the data. In substantive terms, this means that babies born to mothers in poverty, with a previous history of pregnancy problems, do not fare as badly as one would think, given the separate effects of poverty and previous pregnancy experience. Similarly, low birth-weight babies born to poor mothers experience a lesser risk of neonatal death than the separate poverty and birth-weight effects, when multiplied together, might indicate. These interactions indicate that a low birth-weight infant born to a family in poverty, or an infant born into poverty whose mother experienced previous pregnancy loss, does not experience negative effects of poverty during the neonatal period. Because previous pregnancy loss and low birth weight are two of the most important risk factors in infant death and both are easy to identify clinically (most

birth certificates in the United States collect this information), this result implies that such high-risk, poor children are being well cared for by our hospitals. Neonatal intensive care units are organized throughout the United States, and may be responsible for some of this effect (Institute of Medicine, 1973). These interactions also indicate, however, that poverty is related to particularly high levels of neonatal mortality if poor children are not identified as high risk.

In contrast, no attenuation in the effects of poverty upon high-risk infants are found during the postneonatal period (see Table 4). Even high-risk infants would be out of the hospital during this period, and thus subject to the outside environment, including all of the negative consequences associated with a household in poverty. These findings lend support to an often stated characteristic of medical care for children in the United States: differences in the care received by poor and wealthier children tend to be

... least pronounced in the area of tertiary care (which is the most highly specialized

and sophisticated treatment) because major medical centers usually provide for rich and poor alike when health problems have become critical or complex.

It is outside the hospital setting that the system breaks down, especially for the poor, and most especially for children . . . (Keniston et al., 1977:156-7)

Other significant interactions predict that low birth-weight infants who are firstborn (Table 4) and who are born to young mothers (Table 3) tend to experience particularly great mortality.

Finally, given the nonexperimental nature of the present research, the exclusion of variables from analysis which are related to both poverty and infant mortality could have biasing effects upon estimated relationships. A number of such possibilities are discussed below, along with an assessment of the effect of their exclusion upon coefficient estimates; no evidence of serious bias, however, is found.

One variable thus far excluded from analysis is the urban/rural character of the infant's home. Rural families are further

removed from access to health care than their urban counterparts and furthermore, the definition of poverty used does not make an urban/rural distinction. Part of the poverty effect observed thus might be due to the consequences of rural living, rather than to a lack of income. To test for this possibility, we dropped the insurance variable from the equation predicting neonatal mortality (because of limitations in the computer program) and added a residence variable, which indicates whether or not the infant's parents reside in a Standard Metropolitan Statistical Area. As expected, a significant residence effect was found, indicating the negative influence of a rural situation. The estimated effect of poverty, however, is only slightly attenuated and still significantly different from zero.

Prenatal care, the height and stature of the mother, and her smoking behavior are other factors often related to the increased risk of infant death, yet not measured in the present study. Their influence, however, appears to operate via low birth weight of the infant (Gortmaker, 1979; O'Sullivan et al., 1965; Fielding and Yankauer, 1978a) and thus their exclusion should not significantly bias the effects of poverty estimated in the present research, since birth weight is controlled.

10. SUMMARY AND CONCLUSIONS

The present analysis of infant mortality differentials in the United States provides evidence to support a number of commonly stated beliefs: within the white population of legitimate births in 1964-65 in the United States, poverty status of a family is associated with substantial differences in both neonatal and postneonatal mortality. After adjustments are made for the effects of the variables, education of mother, education of father, age of mother, birth order of the child, the mother's previous pregnancy experience, health insurance held by the family, birth weight of the infant, and whether the child was hospitalized at the time of birth, the fact of poverty is associated with a relative risk of both neonatal and postneonatal death almost 50% greater than that experienced by infants not born in poverty.

Before controlling for the effects of other variables, the relative risks of neonatal and postneonatal death associated with poverty are 1.6 and 2.3 (see Table 1). The neonatal relative risk thus is changed little by the imposition of controls, while the postneonatal relative risk changes more substantially. The moderate attenuation in both of these relative risks indicates the effect of controlling a variety of theoretically important and correlated variables in our analysis.

The estimated direct effects of poverty discussed above are substantially larger than the estimated effects of poverty mediated by the birth weight of the infant. Thus, although care of the mother and infant during the prenatal period is important for disadvantaged populations (Institute of Medicine, 1973; Gortmaker, 1979), poverty still, in a variety of more direct ways, exerts a substantial effect upon the well-being of the newborn.

One significant variation detected in the association between poverty and infant mortality occurs among high risk babies during the neonatal period. Such babies who are poor do not appear to suffer any additional risk when contrasted with the nonpoor. This attenuation in risk is interpreted as an effect of generally excellent neonatal hospital care. A similar attenuation, however, is not found during the postneonatal period.

The data concern 1964-65, and social programs in the United States during the ensuing decade have been aimed at eliminating poverty ("The War on Poverty"), and at more equitably distributing health care to mothers and infants (Medicaid, and Maternal and Infant Health Programs). Despite the initiation of these programs, however, differential distributions of scarce resources such as income and health care persist. Recent data on changes in poverty in the United States, for example, indicate that in 1965 "25.5% of U.S. households were poor before taking account of government transfers. Over the whole period from 1965 to 1972, the incidence of household pretransfer poverty dropped by less than one percentage point" (Plotnick and Skidmore, 1975:170). When government transfers (which includes Medicaid and

Maternal and Infant Care projects money) are taken into account, it is estimated that in 1965, 16.5% of the population lived in posttransfer poverty households, while in 1972 this incidence changed to 11.9% (Plotnick and Skidmore, 1975:174).

Although Davis (1977) provides evidence pointing to the effectiveness of Maternal and Infant Care projects in reducing neonatal mortality, less than 13% of the population of live births is represented in these programs, and these include substantial numbers of nonpoor families (Davis, 1977:226). Lack of comprehensive prenatal care may be noted as a persistent problem in the United States over the last decade: national vital statistics data for 37 states and the District of Columbia indicate that the percentage of mothers receiving late (third trimester) or no (or not stated) prenatal care was 12.8% in 1969, and 9.5% in 1973. The corresponding percentages among the black population were 23.5% and 16.4%.

Financial barriers to the receipt of such prenatal care are still significant. As of July 1, 1974, for example, 20 states did not provide prenatal care under Medicaid to first pregnancy mothers (U.S. Department of Health, Education, and Welfare, 1974), and this particular situation has persisted to the present day.

Thus, poverty and inadequate and fragmented health services for poor mothers have persisted over the last decade, and it seems likely that infant mortality differentials—as well as their reproduction via a stratified system of personal resources—likewise will change only slowly. Infant mortality rates have declined significantly in the United States during the last decade, but current estimates of infant mortality differentials by poverty status are not available. In this respect, it is hoped that estimates of relationships obtained with the present data prove useful as baseline data for future studies.

Two distinct yet related policies might be followed to reduce the differentials indicated in the present analysis. First, free and comprehensive health care could be provided to all pregnant mothers and the newborn. The social costs of such a program would not be large; in fact, the

amount spent upon child health resources per capita in the United States is considerably less than that spent upon the adult population, and utilization of these services have not shown the tendency to increase as have adult use patterns (Haggerty et al., 1975).

Second, the more general functioning of families can be supported through the provision of job opportunities and income supports. As Kitagawa (1977) has noted, such improvement of socioeconomic conditions among disadvantaged groups in the population holds the possibility of achieving greater gains in mortality reductions than advances in medical knowledge.

APPENDIX

DEFINING INCOME POVERTY

Income poverty guidelines are based upon those published by the Community Services Administration (1975). The original criteria were adjusted for changes in the standard of living between 1965–75, as reflected in changes in the Consumer Price Index (Community Services Administration, 1975:1–2).

Two changes in definition were made to better suit the research reported here: (1) Since farm-nonfarm family status was not an item asked in the follow-back surveys, all respondents were classified as either in or out of poverty upon the basis of nonfarm guidelines. (2) The income guidelines were adjusted downward because the follow-back survey coded total family (pretax) income into categories (i.e., \$3,000–\$3,999). The lower 15% of the population studied thus was classified as being in poverty—perhaps better termed *extreme* poverty. These guidelines (in 1965 dollars) are listed below:

Family Size	Family Income
1 or 2	less than \$1,000
3 or 4	\$1,000–\$1,999
5 or 6	\$2,000–\$2,999
7 or 8	\$3,000–\$3,999
9–12	\$4,000–\$4,999
13 or more	\$5,000–\$6,999

ATTITUDE AND BEHAVIOR: A SPECIFICATION OF THE CONTINGENT CONSISTENCY HYPOTHESIS*

KENNETH H. ANDREWS
Columbia University

DENISE B. KANDEL
*Columbia University,
New York State Department of Mental Health*

American Sociological Review 1979, Vol. 44 (April):298-310

The paper tests the contingent consistency hypothesis that social pressures reinforce the effect of attitude on behavior. The attitudes and behaviors pertain to marihuana use; the contingent effects tested are those of parents and peers. The data derive from a large-scale two-wave panel sample of high school students. By decomposing the sample according to the adolescents' specific position in the developmental continuum from marihuana nonuse to initiation to continued use, we identified the conditions under which the hypothesis is supported. No contingent effects appeared over time. Reinforcement of the effect of attitude by social pressures characterized adolescents in the second survey who had shifted from being nonusers to becoming frequent users over the six-month follow-up interval. By contrast, group norms did not interact with attitude to affect simple initiation to marihuana use or continuing marihuana use. Peer-related norms had the greatest interactive impact; parental norms had very little impact. Decomposition of a cohort according to stages of participation in a behavioral sequence made it possible to specify when in that sequence contingent consistency is most likely to appear.

The nature of the relationship between attitudes and behaviors has been the subject of recurrent controversy (see reviews by Schuman and Johnson, 1976; Liska, 1974a; Wicker, 1969; Deutscher, 1973). At issue is the observation that self-reported attitudes often have low correlations with the behaviors they are expected to predict. Many attempts have been made to explain inconsistency between attitude and behavior.

In recent years, most explanatory efforts have revolved around the contingent consistency hypothesis, which assigns a crucial role to situational variables in evaluating the observed relationships between attitudes and behavior (Acock and DeFleur, 1972; Clayton, 1972). It is suggested that attitudes do not predict a particular behavior under all circumstances, since there are almost always

situational forces working for and against behavioral realization of the attitudes. The situations are social and refer primarily to perceived group norms. Held by significant others and expressed either verbally or in actions, norms may reinforce or inhibit the effects of attitudes on behavior. Thus, it can be hypothesized that a person will not necessarily behave in a certain way either when holding an attitude or when experiencing social pressure favorable to the behavior, but generally will do so when individual attitude and group norms are mutually reinforcing. Reinforcement of attitude by social pressures implies group differences such that the effect of attitude among individuals experiencing social pressures will differ significantly from its effect among those experiencing little or no social pressure. In a multiple regression framework, group differences are expressed by interaction terms. For this reason, contingent consistency logically requires the presence of significant statistical interactions. That is, it must be demonstrated that the positive effects of attitudes on behavior will be increased in situations that are themselves favorable to the behavior.

However, the contingent consistency

We would like to thank Michael Bucuvalas, Mark Davies, and anonymous reviewers from this journal for their helpful comments and suggestions.

hypothesis has been ambiguously formulated in the literature. In the original formulation by Warner and DeFleur (1969), the statistical tests implied by the hypothesis were not clearly outlined. The authors only stressed that variables that are related both to attitude and behavior may modify the underlying attitude-behavior relationship. Subsequent arguments have revolved around the specific statistical effects implied by the hypothesis, i.e., whether it is supported simply by additive effects of situational variables or whether it requires the identification of interaction effects. There also has been disagreement about the interpretation of the statistical results that have been reported. Clayton (1972:273) concludes in a study of premarital sexual intercourse that he found "considerable evidence to support an additive contingent consistency model." However, Acock and DeFleur (1972:716) and their critics (Susmilch et al., 1975), as well as Liska (1974b), appropriately stress the theoretical importance of significant interactive effects. The results of Acock and DeFleur (1972), on the other hand, have been reanalyzed and criticized for showing only additive effects (Susmilch et al., 1975). Although Liska (1974b) reported a statistically significant interaction between attitude and reference group support in a reanalysis of Fendrich's (1967) data, Schuman and Johnson (1976) were unable to replicate this result using a different analytical technique. After reviewing many existing studies, Schuman and Johnson (1976) concluded that the best evidence thus far did not establish that interaction terms increased the variance in behavior explained by attitudinal and situational variables.

In this paper, we suggest that a respecification of the behavior measure would help reconcile some of the inconsistent findings in the field and would establish when the hypothesis holds. This is a respecification in terms of the specific behavioral stages characterizing a sample, particularly whether the behavior under study is ongoing or just being initiated. All analyses to date have been carried out either on a cross section of respondents interviewed at a single point in time, or on a sample in which attitude is measured

once and behavior is measured independently a short time later. These samples are what we would call "behaviorally aggregated," i.e., they include individuals at various stages of participation in a particular behavioral sequence. These behavioral stages may vary from nonparticipation to initiation, continued participation, or cessation. Attitudes and situations may play different roles at these various stages. The literature on behavioral commitment, for example, suggests that normative expectations can have a stronger impact on the continuation of a behavior than on its initiation, because such expectations often form only after the behavior has begun (Johnson, 1973:397-8). In Johnson's illustration, significant others may hold no preexisting expectations that a person carry out acts of daring, but norms against "chickening out" may subsequently develop. This does not necessarily imply that the interactive effects of expectations will be stronger for continuing behavior than for initiation. The effects of social norms could be largely independent of attitudes. This becomes a matter of empirical test. Such a test is the object of the present paper.

Adolescent use of marihuana, a relatively salient behavior for most young people, is the behavior under study. First, analyses are carried out on an aggregated cross-sectional sample. Subsequently, separate analyses of ongoing vs. newly initiated behaviors are made in a decomposed longitudinal sample in an attempt to disentangle the interactive roles of attitudes and situations in these two different behavioral phases. The results allow us to estimate the contribution made by each behavioral group, i.e., adolescents already identified as users at an earlier period vs. new users, to the attitude-behavior relationship observed in a cross section of respondents. In testing the contingent consistency hypothesis, we consider the norms and social pressures from the two most important socialization influences in adolescence, namely, parents and peers (Clausen, 1968; Kandel and Lesser, 1972). In our own work, we have documented the important role of peers in marihuana use. We have found that peer norms are important correlates of

marihuana use (Kandel, 1973) and are strong predictors of initiation into marihuana use (Kandel et al., 1978). It is well-known, from research that we ourselves as well as others have carried out, that the use of illicit drugs shows very strong intergenerational differences. Parents and peers subject adolescents to conflicting norms regarding its use. Epidemiological studies have documented the striking differences in rates of marihuana use in different age groups in the population. In the most recent survey (Abelson et al., 1977), 38% of 14-17 year olds report ever having used marihuana as compared with 7% of adults 35 years old and over. Similarly, 24% of 14-17 year olds report highly favorable attitudes toward marihuana (e.g., believe that it is harmless and favor no imprisonment for convicted users) in contrast to 14% of adults 35 years old and over (Abelson and Fishburne, 1976).

Parents and peers also differ in the extent to which the adolescent's marihuana use is visible to them. In our own sample, we find that most students who use marihuana report doing so with friends (59%) and without the knowledge of their parents (66%). Friends are therefore in a much better position to apply sanctions to the behavior when it does not comply with their expectations. Students can satisfy contradictory group norms of parents and friends by smoking marihuana with their friends outside the control of their parents. For this reason, we infer that peer expectations should reinforce adolescent attitudes more strongly than do parental expectations.

The particular analytical strategy we have pursued involves the disaggregation of a two-wave longitudinal sample. This has made it possible to specify the potential contribution of distinct component groups to results obtained in a regular cross section of respondents. In addition, analyses on the various subgroups, defined by information obtained at the two different time points, created a synthetic cohort that approximated the processes to be observed in a longitudinal cohort followed over the various phases of marihuana involvement, from nonuse to initiation to longstanding involvement.

METHOD

Sample

The analyses are based on a two-wave panel survey carried out on a multiphasic random sample of students attending public high schools in New York State during the school year 1971-1972 (Kandel et al., 1976). Questionnaires were administered to students in 18 schools at the beginning and end of the school year 1971-1972 at an interval of five to six months. Usable questionnaires were obtained from 8,206 adolescents at Time 1, a response rate of 81%, and 7,250 at Time 2, a response rate of 76%. The samples were weighted to reflect the variable probabilities of selection of schools and homerooms and the response rate of each school.

To protect the rights of participants in the research, no respondent signed any of the questionnaires. Identification and linkage of records between waves was accomplished through self-generated identification code numbers.¹ Using these codes, 66% of all students at Time 1 could be matched to themselves at Time 2 to constitute the T1-T2 panel sample. To correct for biases introduced by the loss of respondents from the panel, the T1-T2 panel sample was weighted ($N=5,258$) to reproduce the distribution of frequency of marihuana use observed at Time 1 in the total adolescent sample and compensate for the loss of certain users.

Measurement of Variables

Marihuana use was measured by two questions asking respondents how frequently they (1) had ever used marihuana,

¹ Matching on the basis of self-generated identification code numbers is a compromise procedure inferior to the use of names. Not only does it reduce the overall rate of matching, but it potentially introduces a bias in the resulting panel sample, since students who do not provide a correct code and cannot be matched are more likely to be drug users than those matched. Thus, 24% of the students who could be matched at Time 2 reported marihuana use at Time 1 compared with 41% of those not matched. Furthermore, the extent and frequency of use also are related to changes in use patterns over a period of time. The greater the frequency of marihuana use at Time 1, the greater the likelihood that the adolescent will remain a user.

and (2) had used in the 30 days preceding each of the surveys (current use). For the latter, a precoded item allowed six response categories, ranging from *not used* to *every day*. Initiation to marihuana use at Time 2 within the nonusing sample was coded as a dummy variable (1=continued abstinence at Time 2; 2=use of marihuana one or more times by Time 2).

Attitude toward marihuana was measured by an unweighted linear combination of three separate variables: attitudes about (1) whether marihuana should be legalized, (2) whether casual, or (3) whether regular use could cause serious physical or psychological harm. The loadings and communalities from a common factor analysis of the three variables supported the hypothesis that they represented a single underlying dimension, general attitude toward marihuana, as their face validity would suggest (Rummel, 1970). Reliability, as measured by Heise and Borhnstedt's (1970) omega, was .74 and .72 at Time 1 and Time 2, respectively.²

The two situational variables measured the extent to which norms in the adolescent's environment favored the use of marihuana. The peer-related variable was the adolescent's report of how many close friends used marihuana or hashish, with five categories ranging from none to all. We assumed that number of friends using marihuana was a fairly accurate measure of the pervasiveness of expectations in the peer environment favorable to marihuana use. The measure of parental norms was based on the adolescents' perceptions of parental tolerance toward marihuana use.

² Omega is a lower bound estimate of the true reliability. Generally, omega provides a closer estimate of the true value than Cronbach's alpha, except when the items in the composite are τ -equivalent (Smith, 1974:507). The formula is:

$$\Omega = 1 - \frac{\sum_{i=1}^n \sigma_i^2 - \sum_{i=1}^n \sigma_i^2 h_i^2}{\sum_{i=1}^n \sum_{j=1}^n \text{Cov}(x_i, x_j)}$$

where σ_i^2 is the variance of each item and h_i^2 is its communality. The denominator is the sum of all entries in the covariance matrix. Data for the scaling process are available on request from the authors. All reliability coefficients in this paper were obtained on the total weighted adolescent sample.

At Time 1, an additive index measured whether each parent is completely tolerant, tolerant only if the adolescent is trying it out, prefers nonuse but leaves the decision to the adolescent, or positively discourages or forbids use (two items; omega=.79). At Time 2, only the measure of perceived maternal tolerance was available.³ The correlation between the two items at Time 1 is .69. First-order interaction terms were constructed by multiplying the composite measure of marihuana attitude by each situational variable.

Five other variables, known to influence drug use from prior research, were included as control variables in the analyses to avoid biased estimates of the effects of the variables of interest. They were: closeness to father (four-item index; omega=.77); peer activity (five-item index; omega=.69); minor delinquency scale (seven-item index; omega=.88); political participation (single item); and number of classes cut (single item). These five variables were included because they represented the significant predictors of marihuana use, both in longitudinal and cross-sectional analyses, from among 14 subclusters of variables selected to measure the effects of intrapersonal, interpersonal and social variables on marihuana use (see Kandel et al., 1978). No interaction terms were constructed for these five variables, and their additive effects, although included in the equations, are not displayed in the accompanying tables.

³ It can be noted that peer norms were measured behaviorally and parental norms attitudinally. We were unable to use parallel measures of norms in the parental and peer environments for two reasons: (1) perceived parental marihuana use, which is parallel to the measure we employ for peers, is skewed so highly that it has insufficient variance for use in the analysis; (2) perceived peer approval of marihuana, which is parallel to the measure we employ for parents, was not present in the Time 2 data set. To ascertain whether the results reported below were an artifact of the way in which social norms were measured, we repeated the cross-sectional analysis reported in Table 1 on the Time 1 sample with parental and peer norms measured attitudinally. The relative effects of parental and peer pressures, both additive and interactive, were similar to those presented in Table 1 (data not presented). We believe that our results are not affected by the fact that peer pressures were operationalized behaviorally and parental pressures attitudinally.

Analytical Strategies

In order to isolate more precisely the effects of attitudes and situations on behavior, parallel analyses were carried out on an aggregated cross-sectional sample and on a longitudinal sample decomposed into the separate behavioral groups that comprise a population observed at one point in time. The short interval (five to six months) separating the two waves of data collection in the survey proved to be advantageous, since it permitted us to identify a population in the process of change and to measure predictors of change at a time closely preceding the change itself.

The analyses on the aggregated cross-sectional sample examined the whole range of marihuana behavior from nonuse to heavy use, as indexed by a quasimetric variable, frequency of current use. The cross-sectional analyses reported in this paper are based on the wave 2 sample for two reasons. A longitudinal analysis described below required that a statistical control for prior participation in the behavior be introduced. In addition, we needed to disaggregate a cross section of respondents into various behavioral groups on the basis of their history of marihuana use. The Time 2 cross-sectional sample was disaggregated into two major groups on the basis of the longitudinal information on marihuana use available from the Time 1 data: one group included adolescents who were nonusers at Time 1 ($N=3,725$); the second group included adolescents identified as users at Time 1 ($N=1,533$).

The identification of these two basic groups allowed us to examine the relationship between attitudes, situations and behaviors in four contrasting conditions: (1) prior to initiation, by examining Time 1 variables as predictors of Time 2 behavior among all Time 1 nonusers; (2) shortly after the opportunity for initiation had occurred, by examining the Time 2 predictors of marihuana use at Time 2 among all Time 1 nonusers; (3) during participation in the behavior, by examining the Time 2 predictors of marihuana use at Time 2 among all Time 1 users; and (4) among continuous users, by examining the Time

2 predictors of marihuana use at Time 2 among those Time 1 users who definitely used marihuana in the five to six month interval between Time 1 and Time 2. As we noted earlier, such a disaggregation makes it possible to identify those parts of the behavioral sequence when interactions between attitudes and norms are most likely to appear. Although we cannot predict with certainty at which point such interactions will be strongest, we expect, based on the concept of behavioral commitment (Johnson, 1973), that contingent effects will have their strongest impact on the continuation rather than on the initiation of a particular behavior.

RESULTS

Test for a Causal Order between Attitude and Behavior

The contingent consistency hypothesis assumes implicitly that attitudes are causally prior to behaviors, or at least that attitudes affect behaviors more than behaviors affect attitudes. This assumption can be questioned, since we know that when actions and attitudes are discrepant, the former can produce changes in the latter (Kelman, 1974). A partial test of the assumption was carried out with a cross-lagged path analysis of the two-wave panel sample (Heise, 1970). Frequency of marihuana use at Time 2 was regressed on both itself and the composite measure of attitude toward marihuana at Time 1, while attitude toward marihuana at Time 2 was regressed on the same two independent variables. The standardized autoregression coefficients of frequency of marihuana use and attitude over time are .57 and .65, respectively. The cross-lagged coefficient of attitude on behavior is about four times the size of the coefficient of behavior on attitude, i.e., .20 vs. .05, although both are statistically significant. The cross-lagged model has failed to disconfirm the presumed causal order of the variables in the contingent consistency hypothesis.

esis involved examining the relationship between attitude and behavior at one point in time. The bivariate cross-sectional relationships between attitude toward marihuana and frequency of marihuana use are fairly high: .49 at Time 2, and .51 at Time 1. This is comparable to the correlation of .53 between attitude of college students toward marihuana and voting for its legalization in a mock election several weeks later reported by Acock and DeFleur (1972:720). Acock and DeFleur attributed the size of this correlation to the salience of marihuana for college respondents. The same explanation may hold for our sample of high school students. The first question to be addressed is whether the relationship can be increased still further with the addition of situational variables indexing reference group norms.

Frequency of marihuana use at Time 2 was regressed on attitude toward marihuana and the two situational measures, first in an additive model, and subsequently in a multiplicative model that included the first-order interactions between attitude and the situational variables. Both equations also included the additive effects of five control variables known to affect drug use.⁴ Results are

displayed in Table 1. As discussed earlier, the contingent consistency hypothesis is supported when the interaction terms significantly improve the fit of the equation. The F-test for each variable is of limited help in making this judgment, because the sample size is so large that almost any improvement, however slight, is statistically significant. Consequently, we have relied partly on the increase in the percentage of variance explained to identify meaningful statistical interaction.

Parental tolerance of marihuana has a fairly weak linear effect on frequency of marihuana use at Time 2. But the effect of number of friends using marihuana, as measured by the standardized partial regression coefficient, is three to five times as large as that of attitude. The effect of attitude, while clearly significant, is not large. The increased variance explained by the interaction terms collectively (7%) is statistically significant ($F=426.9$), as are the two individual interaction effects. Only the effect of attitude by number of friends using marihuana, however, is substantively important. The results appear to support the contingent consistency hypothesis. Norms in the peer group when favorable to marihuana use interact with a positive attitude toward marihuana to produce the highest rates of adolescent

⁴ Inclusion of these five variables alters the coefficients for the variables of interest, but only very slightly. For example, when the five control variables are excluded from the equation in Table 1, the

unstandardized regression coefficient for peers increases from .52 to .56. The one for attitude increases from .07 to .08.

marihuana use. The variable which amplifies the predictive power of adolescent attitudes for behavior describes peer as opposed to parental norms. This result is consistent with the greater visibility of marihuana behavior to peers than to parents.

Longitudinal analysis. The bivariate relationship over time between attitude toward marihuana and frequency of marihuana use is .50, which is of the same magnitude as the cross-sectional relationship. Most longitudinal studies of other behaviors, however, report zero-order correlations of behavior with attitudes which rarely exceed .30 and often fall short of it (Wicker, 1969:65).

The association of attitude and marihuana use at one point in time represents an instantaneous measurement of an ongoing reciprocal process. Many adolescents probably have been using marihuana for some time, so that the attitude may in part be determined by the behavior itself as well as be a cause of it. However, the cross-lagged regression analysis reported above indicates that attitudes affect behaviors more than vice versa. The longitudinal data provide an opportunity to examine the attitude-behavior relation while controlling for prior behavior at Time 1. The cross-sectional equations could be misspecified. Indeed, the situational variables and the interaction terms may reflect the continuity across time of frequency of marihuana use, because this variable is not present in the equation as a Time 1 predictor of itself at Time 2. Frequency of marihuana use at Time 1 was therefore added as a predictor in the equations reported in Table 1. If the main and interaction effects of the situational variables were spurious, they should disappear.

Although the increment in the explained variance due to both interaction effects declines from 7% of the total variance to 4%, it is still statistically significant ($F=296.3$). As in the preceding analysis, the interaction effect for number of friends using marihuana is by far the more important ($F=562.0$). Frequency of marihuana use at Time 1 has a strong net effect ($\beta=.43$) on itself at Time 2 and its inclusion reduces the net effect of number of

friends using marihuana. These results suggest that some of the interaction effects attributed to situational variables in cross-sectional analyses may in fact be accounted for by the continuity of the behavior over time. In general, however, the longitudinal analysis does not alter the conclusions drawn from the cross-sectional analysis in any major way: the interaction effect between attitude and peer norms is still substantively and statistically significant.

Disaggregated Sample: Initiation and Ongoing Behavior

In order to isolate more precisely the effects of attitudes and situations on behaviors, the analyses were carried out separately for the separate groups that comprise a population observed at one point in time. Two major groups were distinguished: (1) the group comprised of nonusers at Time 1, and (2) the group of students who were already using marihuana at Time 1. As noted earlier, this makes it possible to examine the relationships among attitudes, situations and behaviors in four cases: (1) prior to initiation, with Time 1 variables as predictors of initiation in the follow-up interval among Time 1 nonusers; (2) shortly after the opportunity for initiation has occurred, with Time 2 predictors of frequency of marihuana use at Time 2 among Time 1 nonusers; (3) during participation in the behavior, with Time 2 predictors of marihuana use at Time 2 among Time 1 users; and (4) among definite continuous users, excluding from Time 1 users those who had not reported any use between the two surveys since they could not be classified definitely either as continuing users or as stoppers. Predictors in the fourth analysis also are measured at Time 2. The first two sets of analyses are performed on the same respondents. The last analysis is performed on a subset of respondents included in the third. Comparison of the results for conditions (2) and (3) pinpoints which specific group contributes to the interactions observed in an aggregated cross-sectional sample.

Initiation into marihuana use: a new behavior. We could expect the clearest

test of the attitude-behavior relationship to appear when the attitude can be clearly measured before the appearance of the behavior. Onset of marihuana use provides such a test. In the first analysis carried out on the group of adolescents who were nonusers at Time 1, the behavior of interest was initiation. The dependent variable was the Time 2 dummy variable, initiation vs. noninitiation, and the predictors were attitude and situations measured at Time 1, with five factors known to affect marihuana use introduced as controls. Since initiation can occur only among adolescents who have never previously used marihuana, this procedure brings with it a built-in control for prior level of marihuana use. The zero-order correlation between attitude and initiation is .28. Table 2 displays the additive effects of attitude and the two situational measures, together with F ratios and R^2 increments for the corresponding interaction terms. Although both interaction terms are significant, this is largely a result of the large sample size rather than an improvement in the fit of the equation. Interaction effects between attitude toward marihuana and situational variables do not have any importance when predicting initiation of marihuana use.

Extent of new involvement: frequency of use among former nonusers. Two further analyses were carried out among nonusers, in which extent of involvement at Time 2, not merely initiation, was the behavior of interest. A longitudinal

analysis replicated the initiation analysis, with the dependent variable changed to frequency of marihuana use at Time 2. Results were similar to those reported for initiation, with no substantively important interaction effects (data not presented). Such effects did appear, however, in a cross-sectional analysis in which the predictors of the extent of newly initiated use were measured at the same point in time as use itself. The regression analysis predicting frequency of marihuana use at Time 2 among students who were nonusers at Time 1 is presented in the left half of Table 3. Predictors and behavior are *all measured at Time 2*, directly replicating the analyses in Table 1 for a subgroup of the population. As in the overall sample, an unusually large amount of interaction is present: together the interaction effects increase the explained variance by 8% ($F=194.56$). Attitude by itself, which has already been found not to be a strong predictor of marihuana use when other variables are held constant, appears to be even less important when individuals are moving rapidly through the range of participation in the behavior. Thus, a configuration of favorable social and attitudinal forces appears to be highly conducive to rapid involvement in marihuana use. Being a member of a peer group where marihuana use is highly prevalent may facilitate rapid and heavy involvement in marihuana use. This interpretation obtains additional support from a further statistical manipulation of the data. A plot of the

difference between the absolute values of the residuals from the additive and interactive equations against the dependent variable at Time 2 reveals that the interaction terms improve the fit most for respondents with high values on the dependent variable in the Time 1 nonuser subsample. The correlation between this measure of improvement in fit and frequency of marihuana use is .36. This finding indicates that the interaction effects are occurring among adolescents who were nonusers at Time 1, but became frequent marihuana users at Time 2. The fact that the interactions were found to occur at this particular developmental phase suggests that strong social norms together with the appropriate attitude favor extensive involvement in the behavior.⁵

Frequency of use among prior users. The Time 1 nonusers constitute a subset of the total sample represented in the analysis of frequency of marihuana use at Time 2 (Table 1). The complementary group is composed of adolescents (N=1,533) who were already using marihuana at Time 1. This group includes adolescents who used continuously over the follow-up interval as well as some who did not.

The analyses were replicated on the restricted Time 2 sample of adolescents who reported having already used marihuana at Time 1. Again, all variables are measured at Time 2. The results are reported in the right half of Table 3, which is analogous to Table 1. The unstandardized coefficients show that the additive effects are roughly similar to those in Table 1. The interactive effects are miniscule: number

of friends using marihuana accounts for less than an additional 1% of the total variance.

Comparison of the two halves of Table 3 indicates that the total Time 2 variance explained is larger among Time 1 users than among Time 1 nonusers (41% vs. 27%), and that all three predictors have larger additive effects on marihuana use among prior users than among nonusers. Since the variables are all measured at the same time in both subsamples, the increased size of the unstandardized coefficients among Time 1 users may reflect the effect of prior marihuana use on the predictors in a group that has already been using for some time.

Frequency of use among continuous users. Finally, to establish that processes associated with cessation of marihuana use are not confounded with those for continuing use, we replicated the analysis in the subset of Time 1 marihuana users who also reported use between Time 1 and Time 2 (N=955) and hence definitely could be considered continuous users. The results are presented in Table 4. Although the additive R^2 is considerably smaller than among all prior users, the results follow similar patterns. The interaction effects are still very small. There is no evidence of mutually reinforcing effects of attitude and social pressures on frequency of marihuana use among adolescents who were already using marihuana at Time 1 and continued to use over the follow-up interval.

CONCLUSION

The relationship between marihuana-related attitudes and marihuana use is fairly high in the present sample of adolescents. When a measure of group norms is included with attitude in an equation predicting frequency of marihuana use, however, much of the apparent effect of attitude turns out to be spurious. Peer influence, in particular, has a considerably stronger additive effect than attitude. Under certain conditions, perceived extent of drug use in the peer group also interacts with attitude to improve the fit between attitude and behavior.

The strategy of carrying out the

⁵ It will be recalled that no such interactions appeared when the predictors were measured at Time 1. A partial explanation may be that attitudes are changing fairly rapidly in the short follow-up interval. Even with a correction for attenuation, the true Pearson's r in this subsample between Time 1 and Time 2 attitude lies between .81 and .59. We know from the cross-lagged regression analysis that attitudes are unlikely to be modified by behaviors. In situations of rapid change, measurement of an attitude at the same time as the behavior may represent a better approximation of the respondent's attitude during the follow-up interval than a measure taken in the past. The contrast between the two panels of Table 3 further strengthens the interpretation that it is among new users that the interactions occur.

Attitude toward marihuana	.13	(.12)	N.A.	N.A.
Number of friends using marihuana	.38	(.51)	0.6	.000
Parental tolerance of marihuana	.09	(.11)	0.7	.000
Additive R ² = .26				
Total R ² = .27				

^a The following five variables also were included as covariates in all the regressions: closeness to father, degree of peer activity, minor delinquency, political participation, and number of classes cut.

^b The coefficients below were estimated before the interaction effects were entered in the equation.

^c The F ratios apply to the coefficients for the interaction effects, not main effects.

^d The interaction effect for number of friends using marihuana appears in the equation before the interaction effect for parental tolerance of marihuana. Consequently, it is assigned the variance explained jointly by the two interaction effects.

* All coefficients are statistically significant ($p < .05$).

N.A. = not applicable.

analyses on samples decomposed according to the adolescents' specific position in the developmental continuum of marihuana nonuse vs. use made it possible to specify the conditions under which the contingent consistency hypothesis was supported. We specified which type of situational variable had the greatest impact and the subgroup in which the effect appeared. Cross-sectional analyses based on an aggregated sample of adolescents at various stages of participation in marihuana use had shown interaction effects between attitudes and situations. Decomposition of the sample into prior nonusers and users reveals that group norms do not interact with and amplify the effect of predisposing attitudes on initiating marihuana use. In the earliest stage immediately preceding onset of marihuana use, all the effects of situational variables are additive. But interactive effects also do not appear for an ongoing behavior that is already well-established in the repertoire of the individual, in our particular sample for a period of at least six months. Rather, interactions appear specifically among those adolescents who shift from being nonusers to becoming frequent users in the follow-up interval. The interaction effects of perceived parental and peer norms increase the explained variance by an additional 8% of the total variance. Comparison of our results with those of Acock and DeFleur (1972) is instructive. Both studies deal with

marihuana-related behaviors. Acock and DeFleur were criticized (Susmilch et al., 1975) because a reanalysis of their data showed that the interaction effects between attitude and social pressures increased the explained variance by approximately 3% of the total variance, which is not statistically significant for their sample size of 212. Whether the criterion is a large increment in explained variance or statistical significance, our results, especially those for adolescents who shifted from nonuse to frequent use, constitute the strongest statistical evidence for the contingent consistency hypothesis presented to date in the literature.

Movement from the earliest stage of marihuana use to frequent use constitutes a radical change in behavior. Attitudes appear to have only a moderate impact on behavior when less extreme change or no change is occurring, but to be particularly susceptible to reinforcement by social pressures when extreme change is taking place. The findings cast doubt on Liska's (1974b:93) hypothesis that social norms reinforce attitudes only when the object of the attitude consists of people rather than specific behaviors.

The greater influence of peers than of parents may be directly related, not only to the greater reliance of adolescents on peers than on parents for matters related to adolescents' current life styles, but to the greater visibility of certain adolescent behaviors to peers than to parents. Social

pressures can only be expected to condition attitude-behavior consistency when the individual's role performance is readily visible to the members of the group. Especially where deviant behavior is concerned, a lack of visibility or observability can impede social control sufficiently for the behavior to take firm root and depart more and more from the group norms in question (Coser, 1961; Merton, 1957:319-21).

The contrast between the interactive effects of situational factors among prior users, on the one hand, and among new users who are moving rapidly into heavy use, on the other, may help to explain the conflicting findings of earlier studies. Cross-sectional samples, and other samples that do not permit measurement of the behavior at two points in time, confound the effects of situations on initiation vs. continued participation in the behavior. The overall results for a particular sample will depend upon the proportion of respondents who are at various phases, from nonparticipation in a behavior to early or longstanding participation. These proportions will vary in different samples and for different types of behaviors, as will the proportion of initiators participating heavily in the behavior. These intersample differences may account for discrepant findings among studies.

This interpretation needs to be tested further on other samples. The present study cannot tell us whether contingent effects of attitudes among individuals undergoing rapid behavioral change derive regularly from social influences or whether this is true only for the particular behavior and populations studied, namely, illegal use of drugs in adolescence. Ideally, our analyses, which are based on a synthetic cohort, should be measured in one cohort as it progresses developmentally through the various stages of participation in a particular behavior. Despite these qualifications, we are confident that this research has provided important new insights into the usefulness of the contingent consistency hypothesis. The redefinition of a population in terms of its particular developmental stage of participation in a behavioral sequence permits a specification

of the conditions when contingent consistency is most likely to hold.

GOVERNMENT POLICY AND LOCAL PRACTICE*

PAUL ATTEWELL

University of California, Berkeley

DEAN R. GERSTEIN

National Academy of Sciences

American Sociological Review 1979, Vol. 44 (April):311-327

Pressman and Wildavsky's (1973) popular view that government policy becomes ineffectual in the face of local exigencies is questioned. In contrast, using a case study of government policy on methadone treatment for heroin addiction, we show that federal decision making has profound impact even at microsociological levels of clinic life. A model drawn from organizations theory is developed to explain the efficacy of federal action. Policy is seen often to embody conflicting or contradictory demands due to governmental agencies' attempts to coopt or placate interests hostile to new policy directions. Governmental monopsony ensures that competing local agencies acquiesce to the details of federal intentions. But internal contradictions in policies limit or undermine local agencies' resources for gaining compliance from their clientele. Thus compromised policies, effectively translated by federal regulation into local practice, result in dysfunctional adaptations by clients, and the policies "fail."

Introduction

A position currently popular among policy scientists views government policy as relatively impotent in local settings because, it is argued, original policy intentions become diluted in the face of daily exigencies at the local level (Pressman and Wildavsky, 1973). It follows from the Pressman-Wildavsky approach that the apparent failure of many government policies stems not from the faults of the policies themselves, but rather from the complexities of implementation at the local level and especially from the diffusion of power among multiple local decision makers. Such a perspective therefore implies broad discontinuity between governmental policy making and local program outcomes, as a result of essentially

particularistic aspects of local circumstances.

Based on our research on government policy and its implementation in the area of drug abuse, we present a different conceptualization of government policy, which has implications opposite to those of the Pressman-Wildavsky approach. Drawing on organizations theory we demonstrate that under certain specifiable conditions, federal policy can be seen to directly determine local program behavior even down to the microsociological level. The "failure" of local efforts is seen to flow *systematically from the structure of policy making*, especially insofar as contradictory interests, embodied in policy, undermine crucial resources which local agencies require to gain the compliance of their clientele on a day-to-day basis.

Using a case study approach, we attempt to link the macrosociology of federal policy on opiate addiction to the microsociology of methadone treatment, in order to show how the sociopolitical forces which shape government policy subsequently determine the practical realm of daily clinic life. The link between public policy and the clinical Lebenswelt is structured by the managerial responses of treatment agencies to the institutionalization of government regulation.

Our model is developed in the sections below. The material is presented in five stages. The first is an historical overview

This research was supported in part by NIMH training grant #5T32 14640-03, and by USPHS grant #MH 14 583. We would like to thank Mark Baldasare, Phil Bonacich, Oscar Grusky, Eugenia Miller, Katherine Newman, and four anonymous reviewers for advice received during the preparation of this manuscript. We also wish to thank Lewis L. Judd and Audrey Holliday for their administrative support during one part of this project. Finally, we are grateful to the many individuals who, over the five-year course of our research, gave of their time, trust, and intimate knowledge of these problems. The views expressed in the paper are, however, the responsibility of the authors alone.

of U.S. heroin policy. Secondly there follows a more detailed analysis of the policy towards methadone maintenance implemented in the late 1960s. The purpose here is to examine why policy took the form it did, and what this implied for treatment outcomes. A third section goes into the response of treatment agencies to federal regulations and local pressures. The fourth section analyzes the impact of this process upon the clinic milieu, especially upon the actions of addicts and staff. The final section summarizes the practical dilemmas of gaining compliance in the clinical setting as the ultimate result of the policies involved, and generalizes from the specific case-study findings to a more widely applicable model of governmental regulation and its likely outcome.

We have utilized two kinds of data in this research. First, in characterizing clinic and addict life, we draw upon our own work in several methadone clinics (from 30 to 160 clients in size) in one California city. This included ten months of intensive participant-observation research in three clinics (Gerstein, 1975; 1976), detailed, transcribed interviews with a representative sample ($N=100$) of present and past clients of the clinics (Judd and Gerstein, 1975; Attewell et al., 1976), and statistical analyses of program records for five clinics over a four-year period. We obtained comparative data on clinics elsewhere from published ethnographies of treatment settings (Gould et al., 1974; Nelkin, 1973; Soloway, 1974), materials published by program administrators (Dole and Nyswander, 1976; Mandell, 1971); and from our own discussions with treatment managers and personnel in several other cities.

Second, in characterizing government policy, we have drawn upon government publications and upon historical materials including those published by principal figures (Lindesmith, 1965; Musto, 1973; Chambers and Brill, 1973; Finney, 1975; Dole and Nyswander, 1976).

Evolution of U.S. Opiate Policy

Prior to this century, opium and all of its derivatives were available virtually free of legal restriction throughout the United

States. Their use for recreational and a broad range of medicinal and quasi-medicinal purposes was widespread. However under pressure from social reformers, and for supplementary reasons stemming from international politics, a series of federal actions between 1906 and 1920 made distribution and use of many opiates illegal (Musto, 1973). Even physicians were constrained to use opiates strictly for analgesic purposes. By 1938, some 25,000 medical doctors had been arraigned and 3,000 imprisoned because they attempted to prescribe narcotics to addicts (Brill, 1973:11).

Thus with the exception of a few short-lived clinics (1912-1924), addiction effectively was taken out of the jurisdiction of private physicians and became defined as a law enforcement rather than a medical problem (Brecher et al., 1972:116). Thereafter, medical involvement was limited to the Public Health Service, especially its Lexington prison-hospital.

Throughout the 1950s criticism grew over a purely law enforcement approach to addiction, culminating in a 1963 recommendation by a Presidential Commission on Drug Abuse that medical treatments be reconsidered. A technique was developed in 1964, by Vincent Dole and Marie Nyswander at Rockefeller University, based on earlier work by Isbell and Vogel (1949), which involved weaning an addict off heroin and substituting a daily oral dose of the synthetic opiate methadone. The addict entered an inpatient (later ambulatory) facility, received progressively larger doses of methadone until no heroin withdrawal symptoms were evident, and then was expected to take this dose of daily methadone *indefinitely*. Intensive supportive therapy to reestablish ego integration and normal social functioning—especially a steady paying job—ensued, and patients were put on an ambulatory (outpatient) basis, with renewable prescriptions for methadone, once such normal functioning had been established.

The major achievement of Dole and Nyswander in the mid-1960s was not simply their perfection of this clinical technique. Rather it was their gaining legitimation for the medical approach to addiction

as a treatable disease. This legitimization involved a postulated analogy between addiction and chronic diseases such as diabetes. Addicts, it was argued, suffer a permanent metabolic deficiency. Just as diabetics require insulin medication for an indefinite period of time, so addicts require ongoing methadone, for an indefinite period, in order to "cure" their disease (Chambers and Brill, 1973:350). In addition, it was claimed that methadone (a) blocked the addict's craving for heroin, and (b) blocked the addict's pleasure from taking heroin (Dole and Nyswander, 1965; 1966; 1967).

Government Policy and Early Institutional Regulation

Dole and Nyswander not only were faced with the task of legitimating methadone maintenance treatment in the eyes of the general public and fellow doctors. They also faced a variety of institutional actors: the Food and Drug Administration (FDA), the Bureau of Narcotics and Dangerous Drugs (BNDD), and local political officeholders. The early clinical trials with methadone treatment carried out by Dole and Nyswander took place in a context in which legality was unclear, and early researchers took the risk of prosecution and of censure for practicing unethical medicine. In 1962, the Medical Society of the County of New York partially legitimated the treatment of addicts, including prescribing narcotics to them, by ruling that such treatment in a strict clinical research setting was ethical medicine (Nelkin, 1973:41). Such clinical programs later were specifically authorized by a 1965 law passed by the New York state legislature. Nevertheless the legal situation remained ambiguous (Brill, 1973:21-2), and both the FDA and the BNDD attempted to secure their jurisdiction in the area, as we shall explain below.

Critics of Dole and Nyswander attacked methadone maintenance on two bases. The first was that it was morally wrong to give narcotics to addicts. One medical critic argued that methadone researchers were "openly giving addicts narcotics to gratify and perpetuate their addiction" (Ausubel, 1966). The second objection in-

volved the possible diversion or misuse of methadone by addicts. This issue was particularly salient to the BNDD, the federal police agency responsible for controlling illegal drugs. In spite of the New York law, the BNDD maintained that methadone programs were illegal under the 1914 Federal Harrison Act (Nelkin, 1973:48). Although the BNDD went so far as to approach certain clinics and make its views known, it did not take the step of prosecuting the clinics (Brecher et al., 1972: 164). Hence its jurisdiction remained ambiguous until a later period.

The FDA has no legal power to control the practice of medicine. However, it does have certain powers to control new drugs, especially to monitor their production, quality, availability, etc. As methadone clinics began opening in various hospitals, the FDA asserted its jurisdiction by categorizing methadone as an "Investigational New Drug," this despite methadone's use in the U.S. and abroad since 1943. This special status of methadone continued well into the 1970s, even after tens of thousands of cases had shown methadone maintenance to be quite safe under clinical management. However, the invocation and protraction of investigational status gave the FDA a continuing mandate to license and inspect clinics prescribing the drug. The latter police function it delegated to the BNDD in 1970.

Initially the FDA simply required physicians wishing to treat addicts with methadone to obtain permission to use this "Investigational New Drug." However, in 1970/1971 the FDA promulgated a "model protocol" which specified in considerable detail various constraints on, and procedures to be carried out in, methadone programs. As we shall see this protocol had a dual function. Firstly it acted to consolidate the practical control of the FDA over physicians wishing to provide methadone treatment, by detailing program regulations and behavior. More importantly, however, it sought to coopt or placate significant critics of methadone treatment by casting their objections in the form of FDA regulations. For example, the BNDD was given direct control over medication security, and had

veto power over licensing. Similarly the FDA bowed to the interests of medical critics such as Ausubel (1966), and included in the contents of the model protocol a variety of measures (to be detailed momentarily) designed to reassure critics that their specific fears concerning methadone would not be realized.

This response of the federal government, to *insist on its jurisdiction* over a new area, and to *embody in policy itself* the views of a variety of interested and often critical parties, was to have crucial consequences for implementation at the local level. This phenomenon is an important element in our general model of government action. We shall return to this in our discussion below.

Substantive features of the FDA model protocol included the following stipulations:

(1) Minors (under 18) were excluded. This was later modified to allow special exceptions.

(2) Documentation had to be provided of prior and present addiction, and a confirmed history of one or more prior failures of treatment, before an addict could obtain methadone.

(3) Consideration had to be given to eventually discontinuing the drug for patients who had adjusted well to maintenance.

(4) Termination from treatment was required for patients who continued to use narcotics or other drugs, or who exhibited alcoholism or continued criminal activity after entering treatment. Drug use was to be checked by at least weekly collection of urine specimens for laboratory testing.

(5) Prior BNDD approval of any methadone program was required. (See U.S. Food and Drug Administration, 1970.)

It is central to our argument that these and other provisions in the FDA model protocol strongly determined the future course of methadone maintenance. To demonstrate this, we shall first make four points concerning these particulars of the protocol, and then we shall consider why the protocol in general had such an impact on program behavior.

A. The protocol resulted in the virtual exclusion from methadone maintenance of the primary vector of heroin "contagion": adolescents who have themselves only started heroin use comparatively recently, and who rapidly introduce their friends to the drug (Hunt and Chambers, 1976). FDA item #1 above excluded many of these from treatment on age grounds alone. Moreover item #2 above, documentation of prior failures at abstinence, requires considerable addiction history. Long-term addicts who have served jail sentences (which constitute "forced abstinence") are easily able to furnish documentary proofs of prior failure. However younger or recently-addicted individuals are unlikely to have accumulated such documentation. Consequently this FDA protocol stipulation precluded maintenance programs from treating the recently addicted individuals who keep the heroin system supplied with recruits, and instead limited methadone maintenance to a "treatment of last resort." This bowed to the views of those critics who claimed methadone simply addicted heroin users to a new drug. By allowing only long-term, "hard-core" addicts access to methadone, the FDA staved off the argument that it was turning young drug users into permanent methadone addicts.

B. The diabetes analogy of Dole and Nyswander was effectively struck down. Although item #3 above did not require methadone patients to be terminated after a time, it set up the ideal that a successful patient be weaned from methadone and end up drug free. This was in direct contrast to the Dole-Nyswander view of methadone as a lifelong medication like insulin, and instead made the drug-free "graduate" the standard of success. This shift in the criterion of successful treatment of a methadone patient was to have strong implications for the future behavior of clinics.

C. The BNDD's institutional interest was to prevent methadone from reaching the illegal market (Dole and Nyswander, 1976). It had no responsibility for treatment. Yet in order to obtain and maintain BNDD approval, methadone programs were obliged to institute rigorous control, security, and accounting procedures.

Thus security preempted therapy in the design of dispensing procedures.

D. The FDA protocols stipulated a maximum daily dose of 160 mg. Despite assurances that local programs could argue for a higher figure, the FDA succeeded, via this "suggestion," in controlling dosages and making lower doses a measure of better programs. As we shall see below, mean dosage levels were to decrease steadily in subsequent years, eroding yet more of the Dole-Nyswander method. However this FDA protocol item countered charges made by critics of maintenance programs to the effect that methadone would be prescribed in high dosages which would allow addicts to get "high," and hence abet their "moral decay."

At this point we have to raise the issue of why the provisions of the FDA protocol had such a profound and long-lasting effect, even though they were not enforceable as law. The FDA itself was obliged to state that the protocol was "intended only as a guide to the profession," while "modification of the protocol and completely different protocols will be accepted, provided they can be justified by the sponsor" (U.S. Food and Drug Administration, 1970). In more general terms we are raising the issue of why governmental agencies' policies often acquire considerable force even though they are not embodied in law.

First, in the short term, program applicants who were faced with a lengthy and difficult FDA licensing procedure tended to stick closely to the model protocol, rather than risk delay or rejections by diverging from the guide. In the longer term, the FDA guide gained its force because it was adopted by most of the crucial organizational actors who constituted the external environment of the methadone programs. The FDA protocol provided potential criteria for evaluating a program: numbers of drug-free graduates, changes in arrest records, etc. State and local agencies therefore took these as standards by which to assess a program's requests for licensing and refunding.

In addition the FDA protocol became a model for permanent state legislation. (The states *do* have jurisdiction over med-

ical practice.) State laws were usually more restrictive elaborations of the FDA protocol. For example, in California, state regulations required *two* or more documented treatment failures, and proof of *two* years addiction prior to entry into a methadone program, compared with one failure and one year in the FDA protocol.

We see here a process not uncommon in situations where federal agencies set technically-complex safety standards: less-expert political bodies show their concern by toughening up the standards. This often occurs at the behest of state regulatory agencies which increase their areas of jurisdiction and autonomy by arguing for controls which go beyond those already covered at the federal level. Similar phenomena have been discussed in other settings by Becker (1963:147-63). In his analysis of the impact of institutionalization and enforcement upon "moral entrepreneurship," he notes both a tendency for legislators to insert their own interests at the rule-making stage, and the fact that enforcement personnel feel the need to justify their existence, and the goal displacement which often results from this (Becker, 1963:152, 156-62). One can see both of these processes operating in the case of methadone maintenance.

Thus the FDA protocol, many of whose elements were ideals or suggestions, become elaborated into state law. The protocol and the laws then became the bases upon which authorized inspectors judged programs during site visits. In some cases these inspectors were empowered to revoke program licenses. In other cases, which we will discuss below, they simply could discredit programs by feeding negative evaluative findings to the local news media.

In sum, the FDA protocol molded the external environment within which programs operated by providing a standard against which programs could be judged. The ways in which programs responded to this process are the subject of the next section.

Managerial Response at the Program Level

The rapid appropriation of millions of dollars for drug treatment, and the relative

paucity of organizations already in the field, led to a proliferation of programs, as universities, hospitals, community groups, and private corporations responded to the existence of funding (Mandell, 1971; Finney, 1975:20-30; Diaz and David, 1972). Because the FDA invoked an investigational status for methadone, which required that a potential program show evidence of medical and administrative expertise, community-based groups were hindered considerably in acquiring methadone licenses. This frequently led community groups to develop drug-free addiction treatment modalities. In contrast, university and hospital-affiliated groups, and private organizations with medical and bureaucratic expertise, did well in gaining FDA authorization and government funding for methadone. Since community-based drug-free treatment agencies and methadone maintenance programs provided alternative approaches to treatment, and often competed for funding and addict clientele, community agencies frequently became pitted against the more medical-establishment methadone agencies for such resources. In cities where community groups were able to wield political influence, this acted to make local government especially cautious over methadone treatment (cf. Nelkin, 1973:90-2).

Even among methadone programs "range wars" erupted, and a process of monopolization or oligopolization later occurred in many cities (cf. Finney, 1975:25). In the early years, however, there was something of a funding bonanza, and many agencies sought to enter the field. Typically programs were set up as pilot projects, subject to continuation only if acceptable performance was demonstrated.

Programs responded to this situation by developing what we shall term a *reality construction* or *presentation of self* capability in order to convince funding and regulatory agencies that they were doing a good job (Goffman, 1959). Waiting lists were adopted as one indicator of the need for a program, its success in the eyes of the addict community, and, of course, the need for more money. Characteristics of

addicts in treatment, e.g., time in treatment, positive changes in employment status, reduction in criminal activity, also became widely publicized as indicators of success. A program's statistics were compared with others' in order to show its efficiency (Proceedings of the National Conference on Methadone Treatment, 1971; 1972; cf. Thompson, 1967). It took several years to realize that time series data of the type collected by programs were particularly susceptible to statistical "sleight of hand." By 1973, Brill and Chambers (1973:362-3) were complaining: "Unfortunately, not everyone counts everyone when compiling 'retention' or 'attrition' statistics to share with their professional peers, with funding sources, or with the less-than-informed public." Even indices of reduced criminal activity and increased employment proved subject to manipulation or misinterpretation (Holzman and Lukoff, 1976:6ff).

In addition to these positive presentational activities, methadone programs also had to manipulate their public image in order to stave off external criticism. This became progressively more important over the years as state and federal laws gave regulatory control to a variety of watchdog agencies. For example, a California Board of Pharmacy inspector complained in the local press of one program: "It is a failure to the agencies monitoring it, to the agencies administering it, to the patients using it, and to the taxpayers." His major complaint was that program administrators would not define "just what constitutes a successful *completion* of the program" (emphasis added).

We see here the impact of the FDA protocol in ignoring Dole and Nyswander's rationale for indefinite methadone treatment (like insulin). Instead of regarding the fact that addicts were in treatment as itself a success, regulators invoked the FDA ideal of a drug-free addict (weaned from methadone) as measure of success. The newspaper which reported this inspector's complaints subsequently divided the total methadone program budget by the small number of drug-free graduates and headlined their article: "Each 'Cure' Costs Taxpayers \$53,000."

Thus Dole and Nyswander's original conception of methadone treatment was forgotten.

This perilous external environment (cf. Nelkin, 1973:138) and the desire to look good to funding and regulatory agencies increased the importance of manipulating the public image of methadone programs. These presentational needs were reflected in three particular contexts: (A) aggregate movement of methadone dosage levels; (B) numbers of clients admitted and discharged; and (C) staff composition. In each case it will be seen that the programs studied showed increasing sensitivity toward outside regulatory agencies and other potential threats, and hence reorganized or toughened up clinical practices to avoid any possible external criticism.

A. Methadone dosage levels. From the earliest days of methadone maintenance, critics had accused programs of helping addicts get high. Thus one physician attacked Dole and Nyswander: "... they are simply substituting the euphoric action of methadone for the euphoric action of heroin by administering massive dosages of the former" (Ausubel, 1966:949). Equally the BNDD pushed for lower dosages in the belief that dispensing higher ones meant a higher likelihood of illegal diversion. In such an environment, programs' mean dosage levels became strategic symbols of their toughness and desire to wean addicts from methadone. High doses came under public criticism from surveillance agencies, and programs responded by further lowering their dispensing averages.

Consequently, methadone dosage became a pawn in an organizational struggle, its individual impact on each particular addict lost in presentational politics. In response to external agencies there was pressure on clinicians from program administrators to deny addict requests for increases, and to lower stable doses. The result was a steady decline in average dose over the years.

An additional matter, manipulated for similar reasons, involved "take home" methadone. The requirement to attend the clinic seven days a week in order to ingest methadone was first seen as a temporary

measure during a client's initial stabilization. Thereafter, in order to encourage more normalized lives, including employment, clients periodically were allowed to take home and self-administer one, two or more days worth of methadone. However this was a security risk, since take home methadone could potentially be sold illegally. In line with the increasing sensitivity to possible sources of criticism, the clinics studied, progressively reducing take home privilege over the years, made it available to fewer and fewer individuals and hedged its use with greater restrictions.

B. Admissions and discharges. In the early days of the clinics studied, waiting lists existed and program success could be demonstrated by burgeoning numbers of clients in treatment. Some clients continued using illegal drugs, but this was not seen as *prima facie* failure, since the figures showed considerable reductions in drug use relative to untreated addicts (Chambers and Taylor, 1971). However, as regulation intensified, as community media became more critical, and as federal and local funding sources grew more begrudging, program administrators pushed harder for stringent enforcement of rules, backed by detoxification (discharge from the program following stepwise reduction of methadone dose). In 1973 a policy shift was undertaken to toughen up clinical behavior, which resulted in a rapid *doubling* of the rate of termination of clients, as those with records of continuing heroin abuse were expelled from treatment. The new policy caused a precipitous (30%) decrease in total caseloads over the year.

The point here is that administrative fiat, oriented toward external regulatory and surveillance agencies, succeeded in rapidly changing program census. There was no indication based on a study of clinical records that these actions resulted from changed patient behavior during that period.

C. Staffing. In the early days of methadone maintenance many programs utilized exaddicts (i.e., persons currently presumed abstinent) as front-line staff in the clinics. This pattern of exaddict staff-

ing was quite common nationwide, as exaddict peer counselling provided role models for clients, job prospects for exaddicts, and inexpensive labor for programs, all at one sweep (Mandell, 1971). In the clinics studied, physicians, as expensive resources, primarily were involved in signing prescriptions and in performing periodic physical examinations. Doctors did wield considerable power by regulating dosages; however they were seldom involved in therapy, this being the task of the paraprofessional exaddict counsellors.

While some commentators on methadone maintenance have stressed that the impact of government regulation was to limit the role of physicians in treatment (Dole and Nyswander, 1976:2119), our data indicate that the most profound change in staffing policy was a movement away from hiring exaddicts as staff. This has been commented upon at the national level (Espada, 1977), and is borne out in the clinics which we studied, where a steady turnover of exaddict staff in early years turned into a full-scale rout in later years. As we shall describe below, this again took place in response to the program's increasing concerns with rigid adherence to mandated rules, and its need to present an efficient, tough image to the external environment.

In summary, what we see in these several program responses to government regulation is a progressive displacement of organizational goals, away from therapeutic aims per se and toward an increasing concern with manipulation of clinic practices in order to look good to outside agencies, particularly to powerful surveillance and funding agencies. At a more general level we would suggest that this kind of organizational goal displacement is typical of programs heavily dependent on government money or licensing for their continued existence. Since the goal of maintaining the continued existence of an organization is logically prior to that of the instrumental task at hand, there is a constant tendency to become preoccupied with the former at the cost of the latter. In the case of detailed governmental regulation and surveillance this implies the rise of bureaucratic interests in the organization and the subordination of other inter-

ests to the primary one of adapting to one's external environment in order to keep the organization safe (cf. Thompson, 1967; Dole and Nyswander, 1976:2119).

We now shall consider the cumulative effect of these organizational responses upon the experiential realm of daily clinic life.

Clinic Life for Clients and Staff

Once the initial disorientation of entering a new setting has been dispelled, the experience of a patient within a methadone clinic is fundamentally one of regulation, of rules, of specified procedures which have to be carried out: in short, of grown adults in a high school setting. Everyone knows the rules, virtually everyone present dislikes the rules, but everyone's behavior is rule-governed, even if only in grudging ritualistic compliance.

The fundamental business at hand is the distribution of methadone. There is no casualness here. Fixed hours are set—a couple of hours each in the morning and afternoon. Anyone who is late misses his/her methadone. Persons are called singly to a nurse at an enclosed dispensing station. Although client and nurse see one another daily, the client must always produce a special I.D. card, in the ritualistic fashion of military security, here mandated by BNDD. Methadone is prepackaged in coded bottles of fruit drink, of fixed volume to disguise the dosage, which is meant to be a secret to clients and even counselors. Each client must drink in full view of the nurse, and then respond to questions, to assure that the drink has been swallowed; all this also is mandated by BNDD. Methadone dispensing, the basic ritual, occurs seven days a week, 365 days per year.

Other practices are equally mandatory but less regular: especially the "urine drop." Once a week (he/she never knows quite when) each client is approached by a counselor for a urine specimen. The purpose of obtaining this specimen is for detection of illegal drug use. The urine donation (like the dispensing ritual) is a regular reminder of distrust. It bears no relation to the euphemistic privacy of a urologist's

office. The addict enters a bathroom, followed by a counselor. The rules specify that he/she must be watched while urinating into the bottle. Mirrors are even installed to facilitate this surveillance. Some counselors look away, act indifferently, or dissemble a lack of attention, but the underlying rule is strengthened by such interactional camouflage work.

An important activity occurs when a urine sample has shown "dirty"—evidence of residues of heroin, barbiturates, etc. The client, confronted with the report, often denies all knowledge: "... [I]t's a mistake. The test screwed up. ... The counselor messed up the bottles;" protests of injured innocence to save face. The counselor must act peeved: warnings that the next time may be the last, threats of future retribution, occasional real retribution, notice of a (21-day) "punitive detoxification." Since urinalysis only detects a heroin injection from the prior day or two—and then only if the heroin was relatively pure and the urine not too dilute—injecting heroin becomes Russian Roulette. In the context of "probably they won't ask for a drop today," or "I fixed [injected] two days ago, probably it'll turn up negative," being caught is a nasty surprise, an unlucky event, a good reason to be angry.

Another weekly ritual is an interview with the counselor. Again, a degree of interpersonal concern and interest often exists, although counselors have on the average ten minutes per client per week for face-to-face counselling. Occasionally therapeutic relationships blossom. But in each interview a formal mandated agenda of information must be obtained: "Did you work this week?" Engage in illegal activities? Were you arrested, convicted, etc.?"

To these repetitive activities are added an occasional group therapy session, extended personal counseling, a doctor appointment for some physical complaint, and so on. But such activities are only leaven. The essential routines consist of waiting for methadone, giving urine, and checking in with the counselor. Many patients totally ignore voluntary therapeutic offerings. The senior administrator of one program felt obliged to point out to

the press in the fifth year of the program's operation: "We put in a rule eighteen months ago that anybody on the program was to participate in counselling. That rule is still in effect for patients until they and their counselors decide sessions are not needed."

While the clinical experience of the typical client is a one-dimensional exchange of weekly urine for daily methadone, the clinical reality of the staff is necessarily more complex. The backstage operation of a methadone clinic can be seen as involving an interpenetration of three different realities, each with its own rationale and interests. The first involves self-definition, particularly for the counselors and clinic directors, who were at first (1970–1972) virtually all exaddicts, though individuals without heroin experience were later hired. The exaddicts' job credentials were principally their firsthand knowledge of addict behavior, presumed (since Synanon's publicity) to give them special efficacy in drug treatment. Exaddict counselors had to put this folk knowledge in service of a clinical perspective, while shifting their own self-image from down-and-out to upwardly mobile. They had, on the one hand, to convince addict clients of their savoir faire, that they could not be "conned," and, on the other, to establish themselves as paraprofessional clinicians. This was accomplished in part by language and style. Counselors and clinic directors dressed and spoke with a streetwise style, but also with a facile psychiatric terminology: "subconscious motivation," "defense and coping mechanisms," "denial" and "confrontation," etc. This combination set them off from the clientele, without sacrificing their claim to an insider's knowledge of addiction.

A second reality, which all staff shared, was a bureaucratic-administrative one. Each clinic director was sandwiched between the top program administrators far from the clinic, and the day-to-day problems of staff and clients. Through the clinic director came administrative directives, the majority involved with getting paperwork done, new government edicts and inspections, and making sure security was kept tight. Since rules were con-

stantly breached or bent in the day-to-day life of the clinic, and were, in any case, so complex and frequently changed that often it was unclear what rule applied, there was always room for criticism (and grounds for firings) by the administration. Getting the paperwork done, and avoiding or patching up administrative upsets, were constant concerns for the staff.

The third reality involved the day-to-day management of addicts as nonmedical, nonbureaucratic, nonpassive people. A typical day of staff concerns would be as follows (using their own terminology): Client X is being a pain about needing more methadone, is kicking up a fuss about being screwed over, loudly telling anyone who will listen. Client Y is a slick S.O.B. whom the staff would like to get rid of, but whom no one can catch making heroin deals in the clinic, or using heroin. Client Z keeps coming up dirty, but her old man has just gotten out of jail, lives with her, and is shooting up all the time. The staff knows she has two kids, cares desperately about staying in the program, and would go back to dope and hooking if kicked off the program.

The experiential immediacy of concerns like these enables them to compete in the minds of staff with bureaucratic and other demands.

Staff Responses to the Clinical Milieu

It is clear that the staff members' *normal* situation, particularly for exaddicts, was one of profound role conflict. This was exacerbated as bureaucratization progressed, although it was partially "solved" by the steady elimination of exaddicts. The role conflict drew its power from all of the interests working at cross purposes in the clinic. First and foremost, counselors—particularly exaddict ones—sympathized and even identified with clients. Some knew at firsthand that success in the program meant new life chances: keeping a job, gaining status and self-respect, regaining hope. They also knew what involuntary expulsion from the clinic could mean: the extraordinary mental and physical pressures of hustling, seeking dope, pain, finding dope, shoot-

ing, near or actual overdoses. Often superimposed upon this is constant harassment by police and narcotic agents, and emotional and sometimes physiological blackmail as police lock addicts up until withdrawal prompts them to "cooperate." Exaddict or nonaddict counselors were too close to this reality not to be influenced by it. The cold administrative calculus of punishment broke down when the client was known as an individual and the situation into which he/she would be thrust was viewed as abominable.

The first level of conflict, then, derived from the counselor's proximity to the client world, crossed with demands to enforce punitive sanctions. This conflict was not simply a matter of counselor's social background, but was *genuinely organizational in its origins*. Counselors qua therapists were expected to establish supportive relationships with clients. The establishment of therapeutic thrust was and always is predicated upon notions of care and respect for the individual client. A lack of such particularistic solidarity empties a therapeutic relationship of its meaning and force. Nevertheless, due to the increasing concern with the external environment the counselors were increasingly required to be disciplinarians, enforcers of universalistic rules, organizational moralists. The conflict arose from contradictory demands to be particularistic while universalistic, and trusting while punitive.

While counselor conflict derived at one level from opposition between therapeutic and rule maintenance interests, a second conflict involved self-image. Counselors wished to see themselves as persons of status, individuals with skills, and more specifically, professionals able to help others. Perhaps the term *altruistic orientation* overstates the real professionalism involved, but counselors were undoubtedly caught in this imagery. Administrative policies increasingly undermined such bases of self-definition. A subordinate force which thought it knew what was best for addicts could not be tolerated, especially as the watchdog and punitive functions of counselors began to overshadow therapeutic concerns. Thus in addition to having to integrate contradictory pressure

in their *duties*, counselors had to stave off contradictory definitions of their status. Their role as counselor had positive cultural value, while the role of policeman was particularly abhorrent in addict society, in which police and snitches were loathed. The administration, far from euphemizing the punitive, watchdog functions of counselors, left increasingly little doubt that they were there primarily for that purpose. The most cogent testimony to the assault upon counselors' self-images was the terminology used by a senior program administrator, who began referring to counselors as "urine monitors."

Staff response to these cross pressures in the clinics studied varied between demoralization, acquiescence, and hostility. The importance of these jobs for the exaddicts gave the process extra poignancy. Counselling paid comparatively little; but it was generally the first white-collar work exaddicts had had, their first experience of a respectable niche in which they could keep working successfully. Under these cross pressures some exaddicts left early for other programs. Others dropped out, were kicked out, or acquiesced to demands which redefined their role. For those who did leave, the blow often propelled them directly towards their only other social identity: dope fiend. Completing the circle, some later reappeared as clients in the program.

The Client Point of View

In the sections above, we have given our (sociological) view of several changes which took place in methadone maintenance, e.g., shifts in dosages, staff changes, sudden changes in program expulsions, etc., and have tried to explain these changes in terms of program response to its external environment and mandated policies. It is important to realize however that our analytic perspective on these matters is not that of the addicts themselves. While these same topics were constantly addressed in the course of our interviews with addicts, their folk perceptions of these phenomena clustered instead around the apparent arbitrariness of clinic life, especially as

regards disciplinary actions against addicts.

We wish to make two points concerning this addict world view: first, that the addict perspective was a rational response to real phenomena, i.e., that a high degree of arbitrariness did, in fact, exist. Secondly, we wish to show that the addict's world view was readily rendered irrational and indeed seen as one aspect of addict personality pathologies, by staff members who viewed addict responses through a psychiatric framework. The mutual unintelligibility of addict and staff world views is best illustrated in terms of urinalysis requirements and punitive detoxification (i.e., incremental reduction of methadone dose to zero and expulsion from the clinic).

Examining the issue of urinalysis, we find that a high degree of arbitrariness (or luck) is involved in the process. On the one hand, addicts were faced with uncertainty as to what day they would be called to give a urine sample. Thus, being caught with a "dirty urine" was not simply a matter of scientifically catching those clients who were illegally continuing heroin use. Rather it was a matter of being the unlucky one who happened to be caught on a certain day for a urine sample. This arbitrariness was intensified by problems in the technique of urinalysis itself, having to do with variations in personal metabolism and laboratory procedure. Residues of heroin used two days previously might be identified in the urine of one individual, while heroin shot hours before testing might not be detected in another addict. Drinking beer prior to giving a urine sample would often dilute the sample so that no heroin was detectable. False positives were also not unknown in urinalysis: even when urines were split into two portions for separate urinalysis, the results rarely agreed (C. Lidz, personal communication). Thus addicts did not experience urinalysis as an objective system of surveillance in which if one had cheated program rules one was caught. Rather, they experienced urinalysis as a form of unpredictable Russian Roulette. Staff, however, noting the BNDD licensing of laboratories and the high prices for urinalysis, had to take the official line that

urinalysis results were accurate, and a fair method of catching those individuals who broke program rules.

Given the addict experience of the arbitrariness of urinalysis, there was a widespread belief by addicts that staff members switched urine samples, either to protect friends, earn bribes, or hurt enemies. This was often interpreted by psychiatric staff as a magical or paranoid belief system. Similarly a widespread addict response to urinalysis results was to claim that the outcomes were simply wrong. This was seen by staff as denial in the psychiatric sense. Finally addicts tended to respond to being caught with a dirty urine by becoming angry. Indeed, anger is a rational response to a situation where a series of low-probability outcomes (day urine requested, metabolism, accuracy of urinalysis, etc.) all coincide causing the addict to be caught. Yet anger was seen by staff as addicts' refusal to take personal responsibility for their actions.

A similar mutual unintelligibility underlay staff and client views of involuntary or punitive detoxification, where again addicts viewed the punitive process as arbitrary and ill-intentioned. Program rules were fairly specific: if a client continued using illegal drugs for long after entering the program, the client would first be verbally warned, and then obliged to sign a contract agreement that more "dirties" would result in detoxification and termination from the program. This organizational rule reflects federal and state regulations.

As indicated, the timing and results of urinalysis exhibit a degree of randomness. But in addition, an examination of program records revealed that the number of dirty urines permitted before one received a contract varied according to counselor, concurrent level of administrative strictness, frequency or imminence of audit, etc. Even after a contract was written, the actual number of dirty urines tolerated could vary.

Yet even after the contract was deemed violated and detoxification begun, a further mystification occurred. Clients saw the *process* of the 21-day "detox" as *itself* the punishment, rather than seeing

their subsequent *termination* from the program as the *real* punishment, with detoxification merely a technical means of withdrawing methadone prior to termination (Attewell et al., 1976). Although federal regulations set the minimum time for detoxification at 14 days, addicts felt that even 21 days was so abrupt that one suffered severe withdrawal pains. Forty-five percent of the clients interviewed in our interview sample (Judd and Gerstein, 1975; Attewell et al., 1976) objected specifically to the length of detoxification. Allied to this was the knowledge that expulsion from the program—ostensibly the *real* punishment—was manipulable. Addicts could, and did, return to the program very shortly after being punitively detoxified. Detoxified patients were sometimes on the rolls again within two weeks. Thus, addicts saw the punitive response of the program as centering on the physical pains of detoxification, rather than the moral censure of expulsion or exclusion from treatment.

What then was the consequence of this contradiction between staff and addict world views? Given this context of unpredictability concerning detection of illegal drug use, unpredictability of program response, and addict redefinition of the termination process, a significant proportion of clients denied the fairness or validity of the system of punitive governance upon which the clinics operated. Combined with the various humiliating rules, e.g., viewing one urinating etc., this led to many addicts taking an alienated and instrumental view of the program. Many began a cyclical revolving-door pattern of program involvement: repeated entries to clinics, detoxifications due to continued drug use, and subsequent reentries to treatment after weeks or months on the street hooked on heroin. This was abetted by federal documentation rules which enabled expatients to rapidly reenter, while new addicts, who never previously had been treated, would often have to hang on for weeks or months, awaiting documentation. The program, meanwhile, was able to keep up its case census by admitting "retreads," some up to six times in a four-year period.

This type of career virtually coopted methadone maintenance as a complementary adaptation to preexistent street life. Typical street heroin use involves a period of sporadic shooting (injecting) which escalates to a daily fixed-interval schedule, reinforced by the onset or threat of withdrawal. But the body learns to tolerate a given mean level of heroin, and addicts often respond by taking larger doses. This procedure has finite limits, because money and heroin become relatively hard to get in ever-larger quantities. Addicts responded to this, prior to the existence of methadone maintenance, by experiencing withdrawal pains frequently and eventually going cold turkey (withdrawing from heroin), often in jail. Later, the pattern of injecting would start over.

This stereotypical picture of periods of addiction interspersed with periods of abstinence, has become modified by the revolving-door methadone maintenance career. (Some 37.5% of addicts in one program studied showed this career type by late 1974; Judd and Gerstein, 1975.) These addicts entered the maintenance program, reduced their heroin use considerably, and ultimately were detoxified and expelled for not quitting completely. They resumed full-time street use of heroin until their tolerance got too high, legal or personal problems grew unmanageable, or their heroin connection dried up. Then they reentered the program. Methadone maintenance provided a cushion for such people, by helping them control their heroin needs, and keeping them out of prison.

This creative cooptation of methadone maintenance did interfere with those addicts in treatment who were motivated to avoid heroin entirely, and was not exactly beloved by revolving-door addicts, since it involved continual harassment and degradation by a plethora of treatment practices. But as a "rational" response to an institutional pattern which preached treatment and practiced control, this career pattern, of using treatment to buffer the more unmanageable aspects of addiction, is strikingly symbiotic. The encumbered institutional attempt at treating a social problem produced its antithesis in

addicts' use of treatment to solve their own problems.

The Dilemmas of Compliance

We have indicated above that the addict's experience in treatment involved on the one hand a routine of repetitively demeaning rituals, and on the other a series of uncertain and/or irregular surveillance and punitive measures. This combination, we have argued, is demoralizing for addicts, leads to an alienated and instrumental perspective, and does little to encourage respect for the program. One possible explanation for this could be that these negative consequences result from a lack of adequate bureaucratization, rather than a surfeit (cf. Perrow, 1972). In other words, residual particularistic attitudes (constant bending of rules regarding detoxification, etc.) rendered unpredictable an otherwise rational system of treatment as defined by the FDA.

In countering this "underbureaucratization" thesis we have to demonstrate two things. First we shall show that particularism was not some peculiar aberration of the clinics studied but on the contrary was a necessary consequence of the organizational structure imposed on methadone maintenance. Secondly, we shall argue that clinical practices were not hindered by particularism per se, but rather by the undermining of such particularism resulting from increased attention to FDA and state regulations. In explaining these processes we shall use Etzioni's (1961) work on compliance in which he distinguishes between three types of organizations (coercive, remunerative and normative), each of which employs a specific set of tactics in gaining the compliance of its participants.

From our preceding review of methadone treatment, it becomes apparent that programs have difficulties in using any of the typical organizational constraints or compliance mechanisms to control addict-clients. For example, coercive compliance depends above all upon physically restraining an individual from leaving an institution. Even though addicted to methadone, the addict in

treatment does have the option of quitting the program and returning to street narcotics. Thus, methadone programs cannot effectively operate as coercive organizations.

Remunerative compliance requires a set of variable rewards which may be adjusted to match a subordinate's behavior, and hence entice the subordinate to follow organizational rules. Unfortunately, methadone programs' abilities to marshal such rewards were very limited. Therapeutic offerings such as counselling were not perceived as rewards; indeed, we saw earlier that addicts had to be forced to attend counselling sessions. One possible reward structure—allowing methadone dosage to slide up and down according to good behavior—was ruled out by physicians' ethical objections to utilizing medication as a variable reward. The only other meaningful reward, take-home privileges, had been curtailed and made inflexible due to BNDD and other external pressure. Thus there was a paucity of remunerative compliance in methadone clinics.

The third type, normative compliance, was similarly hamstrung. As Etzioni argued, normative mechanisms (e.g., rituals of solidarity, prestige and status rewards, exclusion, moral stigmatization, etc.) only work in a situation where participants have a high degree of commitment to organizational goals. The various degrading and status-deflating aspects of methadone maintenance, e.g., LD cards, urine monitoring, punitive rules, all acted to destroy any possibility of status or prestige rewards and hence undermined the basis for normative compliance.

Normative control was similarly encumbered in terms of its major negative sanction: expulsion and moral stigmatization. There was a contradiction between the use of exclusion or expulsion as a compliance/control device, and culturally dominant notions of medical treatment. Having successfully defined themselves as providers of medical treatment, programs could not exclude on a long-term basis those expelled exclients who had returned to the street and become readdicted. To do so would be to deny a

sick person medical treatment, which bites too deeply into social mores and taboos. Thus, because of the medical definition, programs could neither effectively exclude rule breakers, nor, after readmission, deny them any of the treatment provisions of the program. Methadone programs therefore had to live with their own treatment failures. Consequently, programs totally lacked any effective negative sanctions for normative control of erring subordinates.

In sum, most of the major mechanisms which complex organizations typically utilize for controlling subordinate participants were absent or unavailable in the case of methadone maintenance programs. Programs were therefore unable to mold effectively the behavior of their addict-clients.

In such a situation the only remaining lever for obtaining compliance involved the use of personal loyalties between staff and clients generated in the day-to-day life of the clinic and in counseling sessions. These friendships produced respect and trust, feelings of mutual understanding and personal obligation. To be kicked out of a clinic involved loss of face to some addicts, not because they felt committed to the program per se, but because they had betrayed the personal trust of a specific staff member to whom they felt obligated. To the extent that a counselor believed and acted as though a client was an individual worthy of being trusted—by imbuing the relationship with importance and solidarity—a counselor could impose such a personal commitment upon the client, which might be reciprocated.

The major method of imposing such a commitment and establishing mutual respect involved treating a person individually rather than as a typical case among many. Particularistic behavior thus meant special treatment, making exceptions to rules, doing more than the standard minimum. By being flexible with rules, a counselor could show that he/she cared, understood the client as a particular individual with special problems, and had enough trust to go out on a limb. In a situation where few other bases for gaining compliance existed, for the reasons out-

lined above, the particularism of program staff became a crucial organizational resource for compliance.

How then does this fit into our wider framework? We have shown that particularistic decisions by counselors were made on the basis of, in Weber's term, substantive justice. The historical intensification of bureaucratic routinization in the clinics, in response to external pressure towards strict enforcement of government regulations, favored formal justice—enforcing rules universalistically, without regard to particular circumstances. But the insistence on increasing formal rationality fatally undermined the particularistic basis of clinical compliance. As the counselors were denied discretionary powers, they became simple enforcers of rules, urine monitors, while the clients, treated more and more as cogs in a metered dispensing machine, increasingly were removed from sources of commitment to treatment.

Thus the mounting pressure to comply with the externally mandated rules intensified the contradiction between strict universalistic application of program rules (designed to prevent abuse of methadone), and a particularistic therapeutic outlook designed to change addicts' behavior. As programs attempted to respond to outside agencies by strictly enforcing federal and state regulations they simultaneously became the agents of their own therapeutic demise.

Summary and Conclusion

In this paper we have tried to give a developmental perspective on methadone maintenance and to link macrosociological levels to the experiences of participants. Methadone maintenance was an attempt to reintroduce a medical treatment model for heroin addiction after 50-year history of punitive prohibition. Government agencies, principally the FDA, succeeded in gaining an early jurisdictional mandate to control these medical interventions. Its model protocol redefined the parameters of methadone maintenance away from the original intentions of Dole and Nyswander, and incorporated the ob-

jections of the BNDD and medical critics into its protocol stipulations. Programs had little choice but to accept this redefined model of methadone maintenance. They were in a situation of lopsided dependency upon federal and state licensing, surveillance, and funding agencies, and upon the goodwill of local media and local government. Since all these institutional actors took the FDA protocol as the template against which to evaluate local programs, such programs had to appear to succeed according to the FDA model. Programs made elaborate efforts at manipulating their public image in order to maintain the support of those external agencies. As surveillance intensified, this involved an increasing attempt at strict compliance with federal and state regulations. These efforts in turn led to intense role conflicts within clinic staff, and alienation and mystification among addict clients. The already limited bases of organizational compliance in the clinics became further undermined, and an adaptational client role—the revolving-door syndrome—grew increasingly prevalent.

Generalizing from the particular case of methadone, we can derive certain insights into the workings of government policy in general, and return to the debate with the Pressman-Wildavsky position described earlier. The first thing to note is that the strength of government policy in this area (in contrast to their notion of federal impotence) derived primarily from the monopsonic position of government as buyer of certain services, such as methadone maintenance. In such monopsonic situations where government is faced with a myriad of competing sellers, and where a non-governmental market for the services barely exists, one is likely to find a much greater degree of "potency" to government policy than elsewhere.

Secondly we see that government policy is frequently contradictory in the sense that it embodies conflicting principles of action. In the case of methadone maintenance this involved the multiple goals of limiting methadone to specific subpopulations, and of strictly policing its distribution, while simultaneously attempting to

set up a successful clinical milieu. Such conflicted policies are likely to emerge, we would suggest, in many instances of policy making precisely because of the political context of federal agencies. In our case the FDA, attempting to appease or coopt both friends and foes of methadone maintenance, allayed the criticism of foes via a hedge of restrictive regulations. This attempt by government policy regulations to appease all interested parties is quite general, especially in contentious areas. It is frequently a prerequisite for obtaining the necessarily broad political support required for the passage of enabling legislation, and also stems from the policy bureaucracy's desire to minimize conflict and opposition to its plans. In most cases this kind of policy-making behavior leads mainly to an excess of regulation and lack of flexibility. At its worst, it results in quite incompatible demands being included in policy and placed upon local implementing agencies.

The impact of such compromised policies is particularly severe in contexts of monopsony or lopsided dependence of local agencies on national government. Agencies then have to involve themselves in institutional presentation-of-self, which involves actively selling their ability to perform contradictory tasks, in order to obtain central financing. Any attempt to fight the irrationalities in policy would simply result in some other competing organization receiving funding.

Finally the manner by which these policy demands have their impact at the program level involves a displacement of program goals towards sustaining funding via strict adherence to government regulations and active presentational work. But compromised policies also impact upon programs by restricting their organizational resources for gaining the motivated compliance of subordinates. Many organizations under the best of circumstances find it difficult to develop an effective reward structure and an appropriate form of normative, remunerative, or coercive compliance mechanisms. But under the burden of detailed government regulations such resources may be severely limited, leading to organizational failure due to paucity of rewards. Alternatively, as in

the case of methadone maintenance, government policy may mandate the use of quite incompatible compliance mechanisms, e.g., normative alongside coercive control, in which case the programs begin to unravel from within as they cannot hold the loyalty or commitment of their members. In either case government policy unwittingly forces programs into presiding over their own demise: the closer the programs attempt to obey the dictates of government, the worse become their problems of organizational control.

Thus far from conceptualizing government policy as impotent on the local level and regarding outcome as detached from policy, we recommend, at least in the context of governmental monopsony, a model which emphasizes the power of policy and of its consequences, both intended and unintended, upon local practice.

COMMENTS

"EQUALITY, SUCCESS, AND SOCIAL JUSTICE IN ENGLAND AND THE UNITED STATES": A COMMENTARY AND CRITIQUE

(COMMENT ON ROBINSON AND BELL, *ASR* APRIL, 1978)*

In the lead article in the April 1978 *ASR*, Robinson and Bell present an analysis of the contrasting orientations toward "Equality, Success, and Social Justice in England and the United States." The article suggests some bases for expecting differences between the two societies, and data are analyzed to test these ideas. Although this is an interesting exercise, the article is flawed in ways which lead the authors to conclusions that are not well-supported by their data, and they ignore findings that have a much stronger empirical base. The purpose of this comment is to identify some of the weaknesses in the Robinson-Bell discussion and to suggest some observations the authors might have been led to had they conducted their analysis in a more appropriate manner.

In order to put this discussion in a meaningful context, however, it first will be necessary to summarize the basic ideas in the article. Robinson and Bell state (p. 126) that:

... our first purpose is to uncover the causes of variations in individual judgments about the fairness of equality or inequality. We propose an explanatory model using path analytic techniques.

Our second purpose is to test the generalizability of the model by its application to data from two societies, England and the United States.

They then discuss briefly their reasons for expecting differences in ideas about equality in the two countries and introduce the data set, consisting of responses from 113 residents of New Haven, Connecticut, and 101 residents of London, England.

The dependent variable of primary interest is a five-item Index of Evaluated Equality, the items of which are in normative form ("should," "it would be more fair," etc.). For instance, one item is: "It's fair that rich people who can pay their fines stay out of jail while poor people may have to go to jail for the same crime." In addition, three other subjective measures are used. One is the respondents' self-placement in one of five social classes (upper, upper-middle, middle, working, lower).

Another is a one-question measure of the respondents' sense of personal equity ("In general, do you personally have the standard of living that you feel you deserve?"). The third is a one-question measure of the respondents' perceived achievement of monetary success ("... tell me how close you have come—or think you *will* come—to ... really getting ahead by earning a lot of money"). These three measures are referred to as Subjective Social Class, Sense of Personal Equity, and Perceived Monetary Success.

The analysis consists of examining the associations among these variables and between them and a set of sociodemographic variables: age, race, education, occupation, and family income. The analysis is organized around three general principles. (1) The Underdog Principle: This leads to the expectation that those who benefit from the stratification system's distribution of rewards will be more likely to view inequalities as just. (2) The Principle of Enlightenment: Those who are more highly educated, other things equal, will view inequalities as unjust. (3) The Principle of an Historical Shift toward Egalitarian Zeitgeist: Younger people will be more likely than older people to see inequalities as unjust. Differences between England and the United States are cited as possible sources of deviation from some of these principles.

After presenting a path model, a table of correlations, and a path analysis, the authors reach a number of conclusions. In general, the results are judged to support the Underdog Principle. They are judged to contradict the Enlightenment Principle in the United States but to be consistent with it in England, a finding that seems "to run counter to the widely held idea that British education inculcates elitist values compared with the more egalitarian values of American education" (p. 140). The Historical Shift Principle seems to hold in the United States, but not in England. In addition, the authors conclude that their findings are consistent with the idea that an English cultural belief that theirs is a just society reduces their sense of injustice due to inequality. Similarly, the authors believe that the findings suggest that in the United States the cultural belief that monetary success is equally open to all seems to serve the same function, to reduce the sense of injustice due to inequality. The authors' most sweeping conclusion is that: "Our findings support the generalization that every society, in the face of its particular historical contingencies, provides a rationale, myth or belief, that enables its members to

* Path is significant at $p < .05$, one-tailed test.

Figure 1. Reproduction of Robinson and Bell's Path Model Explaining Evaluated Equality in England and the United States

cope with their position in the stratification system" (p. 141).

These conclusions have a fine ring to them, and they may be true, but, unfortunately, the data presented form an inadequate basis for them. Although there are many technical flaws in the article,¹ these are not our central concern here. Rather, we wish to focus on issues which cast doubt on the inferences drawn from the study and which would remain even if the technical flaws were repaired and the findings remained the same as originally reported. There are four issues relating to the authors' approach to the analysis and their interpretation of the results. These are: (1) the use of a path model the organization of which cannot be

justified, (2) the failure to examine metric coefficients, (3) the confusion between distributional and associational statistics, and (4) the interpretation of nonsignificant results. Each of these will be considered. Then, in a concluding statement, we will reexamine the study's findings from a different perspective.

(1) *The path model.* We have reproduced here one of Robinson and Bell's figures which indicates the structure of their path model and also reports the estimated path coefficients. Perhaps our most basic criticism of their analysis is that the model unjustifiably establishes an order among the four subjective measures which makes Evaluated Equality *dependent upon* Sense of Personal Equity, Subjective Social Class and Perceived Monetary Success. No justification is given for this ordering, and, we would submit, none is possible. All four measures are taken at the same point in time, so no temporal order is involved. There is no more reason to say that Evaluated Equality is affected by the others than there is to say that they are affected by it. The four are actu-

¹ These include: (a) an inadequate description of the sample, including no indication of the sex or age composition; (b) the use of the term *correlation* in numerous places where the reference is to a path coefficient; (c) incomplete descriptions of variables, such as saying that the Subjective Social Class measure is based on two items without indicating what they were or how they were combined.

Table 1. Effects of Sociodemographic Variables on Subjective Measures

ally coequal subjective measures. Only a strange theory of intrapsychic dynamics could possibly justify the use of this model, and such a theory is not offered in the article.

We have used the data Robinson and Bell report in their article to compute the simpler, more defensible model in which Evaluated Equality is dependent on the five sociodemographic variables. The resulting coefficients are reported in the far right panel of Table 1. They are not greatly different from those reported by Robinson and Bell in Figure 2. However, one coefficient that was significant in their analysis is not significant here—the education coefficient in England.² The effect of education on Evaluated Equality is significant in England only net of the other sociodemographic variables and the other three subjective measures. Although the education coefficients are of opposite signs in the two countries (a point commented on by Robinson and Bell), neither is statistically significant. Thus, in England only race and occupation have significant effects on Evaluated Equality, and in the United States only race and age are significant.

(2) *Metric coefficients.* Robinson and Bell present only standardized coefficients, as in their Figure 2 presented here. This is done in spite of their careful attempt to use comparable measures in the two countries.³ Since com-

parable measures are used, and since some variances differ between the two countries, it is clearly important to examine the metric as well as the standardized coefficients. Both sets of coefficients are presented in Table 1.

No particular contrast between the two sets of coefficients is noteworthy in the Evaluated Equality equation, but the Subjective Social Class equation does show a notable contrast. Robinson and Bell point out that Subjective Social Class "is more highly related to objective measures of socioeconomic position in England than in the United States. This is true, for example, of occupation and income, though not education" (p. 136). It is true, of course, that the R² for Subjective Social Class is larger in England. However, the metric coefficient for family income is identical in the two countries (.002), and the occupation metric coefficient is very similar (.013 in the U.S., .016 in England). Actually, the major difference in the two countries is the strong effect of age in the U. S. and of race in England. Robinson and Bell's interpretation of these data as supporting Lipset's and Alford's notions of greater lower-class consciousness in England is hardly justified.

(3) *Associational and distributional statistics.* A major conclusion reached by Robinson and Bell is that in each of the two countries there is a "cultural belief" which functions to soften negative reactions to inequalities. In

² Robinson and Bell use a one-tailed test and the .05 level in determining statistical significance. We have followed this practice also for the sake of comparability when dealing with the tests associated with directional hypotheses.

³ It is, of course, often necessary to restrict one's attention to standardized coefficients when conducting comparative research since the variables are not

always measured in the same metric. We have been limited in this way in some of our own research. In this case, however, the same metrics were used throughout in the two countries.

England, they suggest, it is the belief that the society is basically a just one, and thus one's lot in life is reasonable by standards of fairness. In the U.S., it is the belief in the possibility of "rags to riches" mobility in the stratification system, a belief which tends to legitimize the position of those higher in the system. Within the study, these are indexed by Sense of Personal Equity and Perceived Monetary Success, respectively. There is a lack of clarity in their discussion of these societal differences, however, which makes their case appear to be more persuasive than it is. Although they at times acknowledge that it is the differences in the associations between these beliefs and the sociodemographic variables, in the two societies that is important to their argument, they also make comments that suggest that there are societal differences in the salience of these cultural beliefs. For instance, in their final paragraph, they refer to "the modest difference between the two countries in how widely held these beliefs are" (p. 141). In fact, there is no difference between the two societies in these beliefs. The means for Sense of Personal Equity are 2.46 and 2.33 for England and the U.S., respectively, with standard deviations of more than .9 in both cases. The means for perceived Monetary Success are 2.70 and 3.06, respectively, with standard deviations of more than 1.4 in both cases. Clearly, these means are not significantly different. There are also only nonsignificant differences in the societal correlations between these measures and Evaluated Equality. The correlations with Sense of Personal Equity are significant in both the U.S. (-.38) and England (-.31), and the correlations with Perceived Monetary Success are nonsignificant in both the U.S. (-.15) and England (.03). It is *only* in a multivariate analysis such as reported in Figure 2 that these subjective measures are differentially "functional" in the two countries. We will return to this point in our concluding discussion.

(4) *Interpretation of non-significant results.* Robinson and Bell conclude that their Underdog Principle is generally supported by the analysis since six of the eight path coefficients for race, education, occupation and income in the Evaluated Equality equations have the predicted signs. Yet, as Table 1 shows, only three of those eight paths are statistically significant, even using a one-tailed test at the .05 level (race in the U.S., race and occupation in England). The Principle of Enlightenment receives no support in either country, and the Principle of an Historical Shift is supported by the significant negative age coefficient in the U.S., but not in England. This is hardly strong support for any of the three principles, especially considering that the Underdog and the

Enlightenment Principles call for opposite results for the education coefficient.

Conclusions. It is difficult to understand how Robinson and Bell, faced with these results, reached the conclusions they did. Their conclusions focus, first, on the extent of support for the three principles. As we have just indicated, none of the three receives consistent support, and the inconsistencies, both within and across societies, are not easily explained. And the article does not present explanations for them.

It is clear, however, that Robinson and Bell are more interested in what they call one of their "discoveries," the partial associations between Evaluated Equality on the one hand and Sense of Personal Equity and Perceived Monetary Success on the other, with the sociodemographic variables held constant. We have criticized their use of a path model which makes the other subjective measures "causes" of Evaluated Equality. Yet, it is true that, if a more appropriate analysis is conducted, similar results are produced. In effect, Robinson and Bell wish to test the idea that the correlations between the pairs of subjective measures are a result of their mutual dependence on the sociodemographic variables. Their argument about the intersocietal differences is basically that there is this mutual dependence in the U.S. with respect to Sense of Personal Equity and in England with respect to Perceived Monetary Success, but that the reverse is not true. An appropriate test of this idea is to compute the partial correlations between the pairs of subjective measures, with the sociodemographic variables controlled for. If this is done, the resulting partial-correlations are: in England, $EE/SPE = -.20$, $EE/PMS = .10$; in the U.S., $EE/SPE = .12$, $EE/PMS = .23$. The SPE coefficient is significant in England but not in the U.S., and the PMS coefficient is significant in the U.S. but not in England.⁴

Yet, even if these partial coefficients are viewed as having some limited importance, it is difficult to see why they came to assume such a central place in the Robinson and Bell discussion. Much more massive intersocietal differences appear in the findings, but they pass almost unnoticed. Also, the analysis is not really in a form that is easily interpreted on the basis of the previous stratification discussions which are repeatedly cited. In conclusion, then, we will present a different view of these data which we think would have led the authors in a very different direction.

The basic purpose of the investigation, we

⁴ It may be worth noting, however, that the difference between the coefficients in the two countries is significant in the case of PMS but not SPE.

are told, was "to uncover the causes of variations in individual judgments about the fairness of equality or inequality" and "to test the generalizability of the model" to the two societies. The discussion of the findings is generally couched in terms of social stratification analyses in which such theorists as Lipset and Turner have compared the two societies. Yet there are two variables included in this study that these previous theorists have not dealt with: age and race. There is little basis in previous studies or theoretical discussions to generate expectations of intersocietal differences in the effects of these variables. Yet, the findings suggest massive differences between England and the U.S. in the effects of these variables, and, once they are removed from the analysis, the findings using the more commonly discussed variables of education, occupation and income are also dramatically different than they appear to be in the original report. These differences are worth noting.

In Table 2 we report the reduced form equations in which the four subjective measures are regressed on the two subsets of sociodemographic variables. In the first rows the effects of age and race are reported, followed by the effects of education, occupation and income (which we will refer to as the stratification variables). The full equations, using all five variables are in Table 1. We find that age and race are not particularly important in explaining Subjective Social Class in either country,

although the race path is significant in England. When just the three stratification variables are used, the intersocietal difference with respect to the explanation of variance in Subjective Social Class is similar to that in Table 1. With respect to Perceived Monetary Success, age has a significant effect in the U.S. but not in England, but the three stratification variables again produce very similar results by themselves as does the full set of five variables in Table 1.

However, very different outcomes are found with respect to the other two subjective variables. In the U.S., race has a massive effect on Sense of Personal Equity, but it has a much more modest effect in England. As a result, the R^2 is reduced by over two-thirds when race and age are deleted from the full American equation (compare with Table 1), but by only about one-third in the English equation. When only education, occupation and income are used as explanatory variables, the R^2 's in the two countries are very much more similar than when age and race are included.

An even more dramatic effect is seen with respect to Evaluated Equality, Robinson and Bell's central measure. In the U.S., the three stratification variables explain only .1% of the variance, while in England they explain nearly 15%. Age and race alone explain 32.3% of the variance in the U.S. but only 11.2% in England. Clearly, these are very great intersocietal differences. The traditional stratifica-

tion measures (education, occupation and income) are quite effective in England in explaining Evaluated Equality, but they are not at all effective in the U.S. Conversely, age and race are much more important explanatory variables in the U.S. than in England. Race functions in a similar way in the two countries, but age and the three stratification variables are dramatically different.

Robinson and Bell either did not notice these differences or they viewed them as in some sense less significant than the effects they discuss. The decision as to what is most important to attend to is, of course, the prerogative of the researcher, and we do not fault Robinson and Bell for being interested in cultural beliefs. It is relevant to note, however, that the differential effects of the stratification variables and of race and sex also can be observed in that part of the analysis on which they concentrate so much attention. Given the authors' emphasis on intersocietal cultural beliefs, these differential effects are worth discussion.

The logic of the analysis of the partial relationships Robinson and Bell focus on depends on the differences in the partials in the two countries. In their original analysis, the IEE/SPE partial is significant in England but not in the U.S. and the IEE/PMS partial is significant in the U.S. but not in England. We have noted above that this remains true when a partial correlation analysis is used in place of their original method. However, rather different results are found if the partials are computed using only the three stratification variables. They are: in England, $IEE/SPE = -.24$, $IEE/PMS = +.12$; in the U.S., $IEE/SPE = -.37$, $IEE/PMS = -.14$. Both IEE/SPE coefficients are significant, but neither of the IEE/PMS coefficients is significant. More important, given the Robinson and Bell discussion, the American IEE/SPE is significantly larger than the English, a complete reversal from the conceptualization in the original article. If a similar analysis is conducted, adding race to the set of controlling variables, we get the following results: in England, $IEE/SPE = -.21$, $IEE/PMS = +.10$; in the U.S., $IEE/SPE = -.18$, $IEE/PMS = -.20$. In this case, both IEE/SPE coefficients are significant, and the American IEE/PMS coefficient is significant. However, there is not a significant difference between the IEE/SPE coefficients. In brief, it is *only* when all five sociodemographic variables are controlled that the partial relationships are of the form Robinson and Bell discuss.

It is apparent that race and age are important contributors to the results they report; those results would be very different if age and race were not included. They would even be significantly different if age were not included. The

heavy emphasis in the article on stratification, on inequality defined in terms of class, seems to be misplaced, given these results. Although that is the emphasis to be found in the literature cited, it is not the source of the results reported. Race and age alone explain almost one-third of the variance in the authors' main dependent variable in the U.S. while the stratification variables are wholly lacking in explanatory power, though a very different pattern is found in England. In addition, the partial associations emphasized in the article depend heavily on the use of age and race in the analysis.

It might be tempting to speculate about the reasons for these massive intersocietal differences, but we will not do so for several reasons. First, the basic information about the characteristics of the samples presented in the article is not adequate to justify the exercise. For instance, we do not even know what the age distributions look like in the two samples. Second, the basic sampling design appears to be inadequate for purposes of generating intersocietal comparisons. Not only are the samples small, but they cannot be viewed as societally representative. Third, we are not convinced that the subjective measures used in this study are adequate bases for making such comparisons. Two are one-item and those based on more than one item are not described in such a way as to suggest that they have the desired psychometric characteristics.⁵

All of these are, of course, also reasons to question the adequacy of Robinson and Bell's interpretations of the findings they report. We do believe that their interpretations are inadequately grounded in empirical findings. But, our primary purpose in this discussion is to suggest that, whatever the adequacy of the data base, the paper distorts the findings by ignoring the distinction between race and age on the one hand and the traditional stratification variables on the other and by errors in statistical analysis and interpretation. The

⁵ For instance, the interitem correlations for the items in the Index of Evaluated Equality are reported to average about .2. We are also skeptical that all five items are measuring views of "equality" in the way this term is usually used. One of the items refers to equal distribution of money to all, while the others refer to receiving money according to need, the right of landlords to choose tenants on racial grounds, the differential respect people receive according to occupation, and the ability of some to avoid jail through paying fines. Although the first of these clearly refers to "equality," the others appear to be more concerned with "equity." Besides, their reference to widely varied substantive matters helps explain their low intercorrelations.

basic theoretical notions discussed in the paper, however interesting they may be, remain largely untested. The fact that the paper so clearly suggests otherwise can only delay their effective investigation.

CONFUSION AND ERROR IN KERCKHOFF AND PARKER: A REPLY*

There is one thing with which we can agree in the commentary by Kerckhoff and Parker: The basic theoretical notions discussed in our paper "remain largely untested." How they could possibly believe that we think otherwise, is a mystery to us since we explicitly labeled our work *an exploratory study* at three key places: in the abstract, the description of the data, and the conclusion.

The data set on which we based our analysis was modest by design. We concentrated our efforts on conceptual clarification and index construction, and we created a measure of attitudes toward equality and inequality, an Index of Evaluated Equality (Bell and Robinson, 1978), which is the dependent variable in the article under discussion (Robinson and Bell, 1978). With our small New Haven and London area samples we aimed to test *in a preliminary way* the empirical and theoretical import of this and other measuring instruments and to explore the relationship between the concepts underlying them.¹ Of course, we hope that other researchers will find the Index of Evaluated Equality useful and that they will test it on large, representative national samples.

Having agreed with Kerckhoff and Parker on this, however, we are forced to conclude that there is little else of merit in their commentary. Rather, their objections reveal unreasonable expectations, confusions, or outright errors.

We thank Jonathan Kelley, Bernice A. Pescosolido, Patricia A. Roos, J. L. P. Thompson, and R. Blair Wheaton for their comments on a draft of this reply. Of course, sole responsibility for any errors rests with us.

¹ Additionally, we constructed measurements of alienation (Perkins, 1979; Perkins and Bell, 1979), perceptions of inequality, and perceived achievement of life goals, which we adapted from Meier (1962).

ALLEGED TECHNICAL FLAWS

Inadequate Description of the Sample

Kerckhoff and Parker contend that we do not fully describe our samples and they label this a "technical flaw." In fact, we provided full details on how the samples were drawn in each country; response rates; an assessment of representativeness; means and standard deviations of the demographic variables of age, race, education, occupational prestige, and family income (Table 1); and a description of the racial composition of the two samples (fn. 6). This seems to us an adequate description of data in a journal that reports, as does the *ASR*, a typical maximum article length of ten printed pages.

Furthermore, had Kerckhoff and Parker written us, as other readers did, we would have sent them a 27-page mimeographed account (Bell and Robinson, 1976), the first report we wrote, that might be more appropriately titled, "More Than You Ever Wanted to Know about the Data of the Yale London-New Haven 1975 Survey."

Incomplete Description of Variables

Another "technical flaw" of which we are accused is the failure to fully describe our measure of subjective social class. In fact, the *ASR* copy editor asked us to cut the original, more complete version of footnote 10 where we describe our measures. But, again, if our critics had queried us, we would have sent them a copy of the interview schedule and an explanation. We began by asking an open-ended question to get the picture of the class system as seen by the respondents. After probing their views on the nature of the class structure, we asked, "To which of these classes (as just named by R) do you belong?" If the interviewer then was able to classify the respondent into one of five classes (upper, upper-middle, middle, working, or lower), he or she did not ask the standard closed-answer question on subjective social class. If the interviewer had any doubts, the respondent was handed a card with the five classes printed out and was asked to pick one to describe him/herself.

The Use of "Correlation" in Reference to Path Coefficients

We do use the words *correlate* or *correlation* in a general sense to refer to the fact that variables were shown to be associated, to vary together, or to be in relation as a result of our path analysis. The context makes it fully clear to what we are referring. We note that the practice of Kerckhoff and Parker is to talk

about unspecified "coefficients." Without the context, of course, one could accuse them, as they do us, of confusing the "coefficient" of correlation with the path "coefficient."

The Adequacy of the Index of Evaluated Equality

Inexplicably, Kerckhoff and Parker raise questions about the psychometric characteristics of the Index of Evaluated Equality (IEE), even though we cite a reference (Bell and Robinson, 1978) that could have answered their questions if they had bothered to look it up. Furthermore, they are confused when they question whether the IEE measures equity or equality. We have discussed at some length the difference between these concepts (Bell, 1974); and in Bell and Robinson (1978) we give a full description of the IEE as measuring the social justice of equality or inequality; that is, it measures respondents' *judgments of the fairness or unfairness of specified social equalities and inequalities*.

But Kerckhoff and Parker claim that these "technical flaws" are not their central concern. Rather, they focus on other issues which they erroneously claim cast doubt on the inferences we draw. We take up each of these issues in turn.

ORGANIZATION OF THE PATH MODEL

Kerckhoff and Parker object to the organization of our path model. Specifically, criticizing the causal ordering we propose among the four subjective measures, they argue that such an ordering is impossible since all of these are measured at one point in time. Of course, longitudinal data would be better than cross-sectional data for establishing time priority in a causal sequence of variables. But if we were to require that in the discipline we would have to discount much of current sociology.

Our effort to establish causal direction rests on the use of theory and the heuristic devices of imagined reconstruction of time priority and hypothetical manipulation of variables. In the case of subjective social class and evaluated equality, we assume that identification with a particular class occurs early in the socialization process, as a person's fundamental identity is formed. Judgments about the fairness of equality in the whole society, we assume further, develop later, as a person's consciousness expands and is enlightened by social knowledge. As regards perceived monetary success and evaluated equality, we use hypothetical manipulation of variables. We ask, is it reasonable to expect, if we could alter a person's perception of his or her monetary success, that a

change would occur in the person's judgment of the fairness of equality in the whole society? Our answer is "Yes," because people may generalize from their own experience of success that the system must be fair or from their failure that the system is unfair. To reverse our assumed causal ordering, however, does not work. That is, changing a person's judgment of the fairness of equality in the whole society cannot change the person's belief in his/her monetary success, because the latter is linked to objective facts that are easily perceived, defined by self and others, and classified.

Moreover, even if there are alternative specifications of the path model, it in no way undermines our interpretation, unless it can be shown that some alternative is theoretically more powerful or fits the data better than does ours. Kerckhoff and Parker propose no such alternative on theoretical grounds. Furthermore, their two attempts to conduct analyses which they feel are more appropriate lead them, in the first reanalysis, to find only minor differences from our results and, in the second reanalysis, to conclude that our analysis is correct.

They first propose dropping the three intervening subjective measures from the model (see their Table 1). They find no difference from our results except with respect to the effect of education on evaluated equality which is no longer significant in England. (They fail to say that, even in the case of education, the effect barely fails to reach significance, $p < .06$, and that the difference between England and the U. S. in the effect of education remains significant, $p < .05$.)

The second analysis, which Kerckhoff and Parker propose later in their commentary as an alternative to assuming a causal order among our subjective variables, involves the computation of partial correlations between pairs of subjective measures when the five sociodemographic variables are controlled. They conclude from this: "Yet, it is true that, if a more appropriate analysis [meaning theirs] is conducted, similar results [to those of Robinson and Bell] are produced." Thus, even when Kerckhoff and Parker assume no causal order among the subjective variables, they support our conclusion that the sense of personal equity and perceived monetary success are differentially related to evaluations of equality in England and the U.S.

METRIC COEFFICIENTS

We are criticized for not examining metric, as well as standardized, coefficients. Although we agree that, generally, it is wise to report both metric and standardized coefficients, two

considerations led us to present only the standardized coefficients. First, although the measures we employed had similar wordings in the two countries and although we believed that they measured the same underlying constructs in both countries, we did not know how much faith to put in the equivalence of scoring of measures.² For example, in scoring subjective social class we were not willing to assume that the distance between the working and middle classes is perceived by respondents to be the same in England as it is in the United States. Therefore, we adopted the cautious procedure of reporting only standardized coefficients. This procedure, ironically, also was adopted by one of our critics when he, too, was faced with differences in measures in comparing England and the United States (Kerckhoff, 1974:794; 1978:597).

Second, Hargens (1976:252) recently has argued rather convincingly that standardized coefficients may be more appropriate than unstandardized coefficients in cross-national studies employing stratification variables. This is because standardized coefficients take into account differences between countries in the spread or variance of variables, and, thus, measure the position of the individual "relative to others in the society."

But these considerations aside, what does Kerckhoff and Parker's criticism amount to? For our main dependent variable, evaluated equality, they find "no particular contrast between the two sets of coefficients." They might have stopped there, but they keep comparing their metric with our standardized coefficients until they do find a difference. This is in the contribution of occupation and income to the explanation of subjective social class. But they distort our interpretation. Obviously, we were talking about the *relative* contribution of the independent variables to the explained variance in subjective social class. Occupation, with a direct effect of .38, is a relatively more important variable in England than in the United States where the direct effect is .25. Similarly, family income is somewhat more important as a variable in England, .21, than in the U.S., .16.

We note that, later in their commentary, Kerckhoff and Parker do the same thing that they criticize us for doing. They use not the metric coefficients but the *relative* contribution of independent variables to the explained variance in the dependent variable when they conclude, "Age and race alone explain 32.3% of

the variance [in evaluated equality] in the U.S. but only 11.2% in England. Clearly, these are very great *intersocietal differences*" (italics added). We are puzzled. Why do they criticize us for doing exactly what they do themselves?

ASSOCIATIONAL AND DISTRIBUTIONAL STATISTICS

Kerckhoff and Parker accuse us of confusing associational and distributional statistics in our analysis. In fact, they twist our words into something we did not say and then criticize us for not saying what we actually did say. With respect to country differences in the *distribution* of the cultural beliefs of personal equity and perceived monetary success, they mention that we refer to "the modest difference between the two countries in how widely held these beliefs are," and then they stress that there is *no* difference. There *are*, in fact, differences in our samples, although they are small, which is precisely what we meant in describing them as "modest."³ In the case of personal equity, we say (p. 133) "the two samples are remarkably similar on this variable." In the case of perceived monetary success, however, there is a small, but significant, difference ($p < .05$, one-tailed test) between the English and American samples, contrary to what Kerckhoff and Parker say.

They conclude this point by saying, "It is *only* in a multivariate analysis such as reported in Figure 2 that these subjective measures are differentially 'functional' in the two countries." That, oddly enough, is precisely what we said: "what is crucial is not the modest difference between the two countries in how widely held these beliefs are, but the difference in how they differentially function to support egalitarian attitudes" (p. 141).

INTERPRETATION OF NONSIGNIFICANT RESULTS

Kerckhoff and Parker claim that we do not take account of the significance of results in evaluating support for and against our three principles. They say with respect to the underdog principle:

Robinson and Bell conclude that the Underdog Principle is generally supported by the analysis since six of the eight path coefficients for race, education, occupation and income in the Evaluated Equality equations have the predicted signs.

³ We note that Kerckhoff and Parker also use the word *modest* to mean "small," as in their statement, "In the U.S., race has a massive effect on Sense of Personal Equity, but it has a much more *modest* effect in England" (emphasis added).

² See Przeworski and Teune (1970:91-131) for a discussion of equivalence of meaning when identical questions are used in cross-national research.

Yet, as Table 1 shows, only three of those eight paths are statistically significant, even using a one-tailed test at the .05 level. . . .

First, they have again misstated us. We did not make predictions for the education coefficients under the underdog principle (pp. 128-9) but under the principle of enlightenment (p. 129). Although we did use eight coefficients in evaluating the underdog principle, they were for race, occupation, income and subjective social class in both countries.

Second, Kerckhoff and Parker claim that we simply summed up the signs of the path coefficients and totally ignored the significance of these. They present their conclusion that only three of eight paths predicted under the underdog principle are significant as if this were something that resulted only from their own analysis. In fact, we reported the significance level of these coefficients both in our Table 2 and in the path model presented in our Figure 2. We also explicitly stated which coefficients were significant in the text (p. 139).

Third, Kerckhoff and Parker imply that we are being methodologically lax in using one-tailed tests of significance on these data. Not so, since we clearly predicted direction beforehand using the underdog principle. Thus, a one-tailed test is entirely appropriate.

Fourth, we ask at what point Kerckhoff and Parker would have concluded that the underdog principle is supported by our data. They seem to require that all eight of the predicted coefficients be significant. This is an unreasonable expectation, especially because overlap among different stratification dimensions in a society functions against all of the coefficients being significant. Rather, an appropriate test of the overall support for the underdog principle is the binomial probability of obtaining three or more significant results in eight attempts when the probability of obtaining a significant result is fixed at $p = .05$. In other words, how likely is it that we would obtain as many as three paths which are significant at the .05 level in eight trials. From the binomial probability tables reported in Hays (1973:880), we find that this probability is $p = .0058$, indicating that, overall, the underdog principle is supported ($p < .01$).

Another test of the underdog principle is the F test for the significance of the R^2 statistic obtained when evaluated equality is regressed on the four hypothesized independent variables taken together.⁴ By this test, too, the underdog principle is supported in both countries.⁴

⁴ Kerckhoff and Parker also claim that we overstated the level of support for the enlightenment principle. This claim is made, however, on the basis

SPECIFICATION OF THE PATH MODEL

In their concluding remarks Kerckhoff and Parker make their strongest assertions against our findings and offer a reanalysis of our data. They argue that our analysis, because it includes the variables race and age, is not in a form that is easily interpretable in terms of the "traditional stratification measures (education, occupation and income)." We find this argument lacking on both theoretical and methodological grounds. We have argued elsewhere (Robinson and Kelley, 1979) that there is no theoretical or empirical justification for assuming that the allegedly traditional stratification variables are the only bases of stratification in society. Because some theorists may not have dealt with race and age as stratification variables by no means precludes our doing so. Moreover, there is ample justification for thinking of race and age as differentiating the population into categories of people who are unequal with respect to conditions, opportunities, and treatment and there is empirical evidence to indicate that race and age do not simply reduce to one of the "traditional" stratification dimensions when these are controlled (e.g., Duncan, 1968; Riley et al., 1968-1972). Furthermore, we provided a priori sound theoretical grounds for expecting race (the underdog principle) and age (the historical-shift principle) to have important effects on evaluations of equality. Kerckhoff and Parker offer no theoretical justification for eliminating them from our model except to make the debatable assertion that they are not usually analyzed in such a context.

Kerckhoff and Parker's false dichotomy between the traditional stratification variables and race and age leads them into methodological difficulties that make their concluding remarks dubious. First, they do a reanalysis, consisting of separate regression analyses, in which race and age, on the one hand, are contrasted with education, occupation, and income, on the other, in their effects on the intervening and dependent variables in the two countries (see their Table 2). In conducting these separate analyses they repeatedly contrast the effects of these two sets of variables as though there were no joint effect of these which might influence the uncontrolled path coefficients and R^2 's. Because race and age are correlated with the three "traditional" measures of stratification and because all five of the variables under consideration have effects

of their reanalysis of our data (Table 1) in which three of our variables have been omitted. Their model (and others they present in Table 2) is underspecified and, thus, results in biased coefficients.

on at least one of the intervening or dependent variables, there is no way that one can adequately compare the relative effects of these two sets of variables without including both sets in the model. For example, when they report the proportion of variance explained in evaluated equality by race and age, some of this effect must result from the fact that age and race are correlated with education, occupation and income, which are, in turn, correlated with evaluated equality.

In a second reanalysis, Kerckhoff and Parker report the results of computing the partial correlations between pairs of subjective measures when only the three "traditional stratification variables" are controlled. Although they had earlier concluded that when the five sociodemographic variables in our analysis are controlled, this "more appropriate" analysis supports our findings, they now find that controlling for only three of these variables results in some differences with our results. First, they stress that age and race have an effect on some of our independent variables and especially on our dependent variable in both countries. Second, they say that when these variables are omitted from the model one of the two country differences is not the same as we reported. Of course it is not the same. They have biased the results in both countries by excluding variables that they themselves admit are important determinants of other variables in the model (e.g., Griliches and Mason, 1973; Hanushek and Jackson, 1977; Koutsoyiannis, 1973:245-8).⁵ Additionally, since age and race are differentially influential in England and the U.S., to omit them makes any country comparison spurious.

CONCLUSION

There is little left of the criticisms made by Kerckhoff and Parker. True, our samples are small and inadequate for setting the parameters of intersocietal differences. That is why we refer to our study as "exploratory" and why further investigation should be encouraged—not discouraged—by our preliminary findings. The findings, as Kerckhoff and Parker say, are theoretically interesting.

We are not persuaded by the rest of the Kerckhoff and Parker critique. Much of their analysis, which they consider "more appropriate" than ours, simply supports our findings

and interpretations or produces only slight differences from them. Where they believe they have found some real differences between their results and ours, they have biased their findings by omitting theoretically and empirically important variables. As a result, their models are less specified, less sophisticated, and less genuine than ours.

Thus, we stick by our original conclusion:

Our findings support the generalization that every society, in the face of its particular historical contingencies, provides a rationale, myth or belief, that enables its members to cope with their position in the stratification system. Such a rationale invites people to accept and condone existing inequality as generally just and reasonable. The invitation, however, is not always accepted, as our data show, by young, enlightened or, especially, underprivileged members of society. (p. 141)

there appears to have been a reversal in the relative rate of unemployment for blacks and whites. From 1940, black unemployment exceeds white and climbs rapidly to the current two-to-one ratio. The reversal took place some time during the 1930s. (1976:35)

Despite its engaging character, this conclusion is necessarily suspect because Bonacich has used two different data sets, one for the years prior to 1930 which shows a lower unemployment rate for blacks, and another for the years since 1930 which shows an increased employment rate for blacks. In fact, on examination we find that, taking just the evidence presented by Bonacich, the "reversal" is a function of the switch in data sets and that we do not have any basis for analyzing the reversal in terms of social or economic processes which occurred in the 1930s.

The two data sets used by Bonacich differ both in whether they include males and females and in how they define unemployment. The first set, for the years 1910, 1920, and 1930, reports the percentage of white and black males "not gainfully employed." The second set, for a series of years since 1930, reports the black and white "unemployment rates" for males and females combined (cf. Killingsworth, 1968).

These two sets of data can be used in a time series analysis only if the following two assumptions can be made: first, that social and cultural factors affecting employment operate on females in the same manner in which they operate on males across races; and second, that the index *not gainfully employed* measures the same thing as the index *unemployed*. The first assumption is contradicted by the data presented in Table 1.

If cultural factors were operating uniformly on the black population, that is, across sex categories, we would expect to find both black males and females to have either consistently higher or lower participation rates than do white males and females. We see, for the sam-

ANOTHER LOOK AT THE BLACK/WHITE TREND IN UNEMPLOYMENT RATES

(COMMENT ON BONACICH, ASR FEBRUARY, 1976)*

Edna Bonacich (1976), in her article "Advanced Capitalism and Black/White Relations in the United States," builds an elaborate historical account of why blacks were once *less* unemployed than whites and then lost that advantage. Her argument is based on data which, she claims, show that

ple years 1960–1975, that while black males have lower labor force participation rates than their white male counterparts, black females have consistently higher participation rates than white females. These figures indicate that it is misleading to mix employment data based on males only with that based on both males and females in a time series analysis. Any trends that result from such an analysis are likely to be due to differences in the data bases rather than historical developments.

The second assumption creates additional problems. Although the percentage *not gainfully employed* and the percentage *unemployed* might appear to be very similar figures, there are crucial differences in how they are used in census tabulations. As used in the census, not gainfully employed measures the percentage of individuals over a certain age who are not employed,¹ and would include housewives, students, and others who are uninterested in working, along with those who wish to work but are unable to find jobs. The unemployment rate, on the other hand, gives the percentage of the civilian labor force currently seeking but unable to find jobs. The civilian labor force, made up of all individuals who are either employed or currently seeking employment, does not capture housewives, students, or the discouraged who have given up searching for employment.

Table 2 presents the percentage of the population not gainfully employed for the years 1910 to 1970, while Table 3 shows the percentage of the civilian labor force unemployed for the same years. The differences in the ratios of the two tables confirm that two different processes are being measured, and that the data are not comparable. As an example, notice that Table 2 gives the black/white ratio of not gainfully employed for 1950 as .99 and for 1960 as 1.02, a minor increase. Similarly, Table 3 shows the black/white ratio of unemployment for 1950 as 1.73 and for 1960 as 1.85, also only a modest increase.

If, however, we were to create a new table which used data on not gainfully employed for the years 1910 to 1950, and the unemployment figures for the years 1960 and 1970, the black/white ratio for 1950 would be .99 and for 1960 would be 1.85. This change would appear as an alarming increase indeed, and based on these ratios alone we might be led to build an analysis of what cultural and economic changes took place in the 1950s to account for

Table 2. Percentage of Population Not Gainfully Employed, 1910–1970

the growth in the relative unemployment of blacks. But this argument would be an erroneous one because the increase is due only to the data used in constructing the table, not to historical processes which may or may not have occurred in the 1950s. This flaw is exactly the defect in Bonacich's presentation, except that she switched data sets in the 1930s time period instead of the 1950s.

Because of this misapplication of the census data, we are forced to reject Bonacich's conclusion concerning the relative unemployment of blacks and whites. The question which she raises, however, concerning whether blacks were ever less unemployed than whites but somehow lost that advantage, can be pursued with existing census information. Two decisions must be made in advance, however. First, it is necessary to decide whether to use data based on males only or on both males and females. Since it was shown earlier that cultural factors operate differently on males than on females, I believe that a strong argument must be based on figures which include both

All figures based on decennial census data.

¹ See, for instance, the discussion on methodology in U.S. Bureau of the Census, *Historical Statistics, Colonial Times to 1970*. The census data actually lists the percentage who are employed, but the percentage not employed is easily obtained from this.

males and females. It is much more powerful to be able to demonstrate that the black population as a whole has a greater difficulty finding employment than the white population, than it is to show that black males have greater difficulty than white males. Demonstrating only the latter leaves open the issue of possible family structure differences between blacks and whites, that is, the possibility that black households rely more heavily on the female as the principal wage earner. The finding that the black population as a whole suffers high rates of unemployment in comparison with the white population is a substantial result which could not be refuted by arguments based on differences in family organization. The data presented here, therefore, are based on figures for both males and females.

Second, it is necessary to decide whether to use percentage of population not gainfully employed or percentage of civilian labor force unemployed. These data sets are presented in Tables 2 and 3, respectively. When the percentage of the population not employed is used, the data do not support the hypothesis that blacks have a greater propensity not to be employed than do whites. For 1950, 1960, and 1970 the black/white ratio appears to stabilize at around 1.0. This means that the percentage of blacks without jobs is very close to being equal to the percentage of whites without jobs.²

However, presented on this basis, the data do not capture what we are really trying to measure. The fact that the same percentage of blacks as whites do not hold jobs tells us little about the processes in the labor market. It is possible, for instance, that 50% of the white population either need or wish to be employed, and that 45% of the white population are able to find jobs. Among the black population, however, 85% may need or wish to hold jobs, perhaps due to lower individual income and the need to increase total family income, but only 45% may be able to find employment. In this case, the black/white ratio based on the percentage gainfully employed will be 1.0, but it will reflect neither the high need for jobs in the black population nor the low rate of success in obtaining employment.

The percentage of the civilian labor force unemployed does a much better job of measuring the differences between the black and white employment patterns with which we are concerned. These figures tell us the percentage of

the labor force (those individuals who are employed or seeking employment) which is unable to find work. The 1960 black/white ratio of 1.85 tells us, for instance, that among blacks and whites in the labor force in 1960, the proportion of blacks unable to find jobs was almost twice the proportion of whites unable to find jobs.³ Since the unemployment rate does not include individuals who have become discouraged and have ceased looking for employment, and since these individuals are thought to be disproportionately black, these ratios, at least for the more recent years, are probably minimum estimates of the black/white differential in unemployment rates.

The ratios of black/white unemployment rates shown in Table 3 support the hypothesis that blacks were once less unemployed than whites, but that a reversal in this pattern took place. It appears that some time in the 1930s the ratio reached 1.0, indicating equal unemployment rates for the two groups. In 1940 the ratio was 1.18, which means that blacks had only a slightly higher unemployment rate than whites. By 1950, however, the ratio had jumped to 1.73, representing a substantial increase in black unemployment relative to white unemployment. It appears, then, that an attempt to explain the relative increase in black unemployment would have to seek historical explanations in the 1940s rather than in the 1930s as Bonacich argues. Quite possibly these explanations would have to take greater account of the dynamic impact of employment patterns during World War II and its aftermath, and of the intensified migration of blacks out of southern agricultural employment.

The data presented here have demonstrated that Bonacich's elaborate historical analysis is based upon an inappropriate use of census data. Her conclusion about the actual timing of shifts in the pattern of black unemployment in relation to white unemployment is due to the switch in data sets which she makes. Even though a corrected view of the unemployment rates for blacks and whites for 1930 to 1970 does reveal that blacks were once less unemployed than whites, but then lost that advantage, the historical implications of this shift need to be interpreted in terms of the time period in which it actually occurred.

Kay Oehler
Washington University

² This is true even when we consider males only, as Bonacich did. The black/white ratios for males only are: 1910: .65; 1920: .86; 1930: .82; 1960: 1.07; 1970: 1.21.

³ These figures are based on decennial census information. When yearly census data are used, the black/white ratios for 1950, 1960 and 1970 are higher. They are 1.84, 2.08, and 1.82, respectively.

STILL ANOTHER LOOK AT
 BLACK/WHITE UNEMPLOYMENT:
 REPLY TO OEHLER*

In her comment, Kay Oehler states that I made several errors in my article, "Advanced Capitalism and Black/White Race Relations in the United States." At the outset let me say that the idea that the black/white unemployment ratio shifted in the mid-thirties and rose to a more or less stable level in the 1950s is not original to me. The reader will note that I cited Killingsworth on the point. Killingsworth did not invent his statistics, and indeed Oehler presents some of the same figures in her Table 3. They show a lower black than white unemployment level in 1930, a shift to a higher black than white unemployment rate in 1940, and a rise to a more or less steady relative black disadvantage in 1950, 1960, and 1970. Even Oehler ends up agreeing that this was the basic pattern.

Oehler accuses me of two methodological errors and a substantive one. Let me deal with each of these in turn.

1. Sex Differences

Her first point is that I confuse total unemployment figures with unemployment for males only. She makes a valid point that male and female labor force behavior are distinctive. Her own Table 1 shows a rise in both black and white female labor force participation in recent years, while the figures for males in both groups have fallen. White female rates have

increased more rapidly than black, while black male rates have fallen more precipitously than white. These discrepancies suggest that we should not combine the sexes, but keep them separate in our calculations since, as in this case, the totals may mask important trends. Indeed there are good theoretical reasons for doing so in that females have played a cheap-labor role not dissimilar to blacks, and have been subject to some of the same historical pressures to exclude them.

Table 1 shows unemployment rates for whites and nonwhites from 1948 when they were first collected on an annual basis by the Bureau of Labor Statistics. As can be seen, the two-to-one ratio does appear in the mid-1950s for the total groups, but emerges earlier and more severely for nonwhite males. The lesser differences between the two female groups may reflect pressures on both not to participate in the labor force at all.

Since these figures are somewhat confusing in terms of showing a distinct trend, we need to go back to the census for earlier information. Census labor force data are not completely consistent with those of the Bureau of Labor Statistics (U.S. Bureau of Census, 1975:122), but during the critical period, from 1940 to 1950, they reveal a nonwhite/white unemployment ratio for males of 1.23 in 1940, rising to 1.70 in 1950. The corresponding figures for females are 1.11 in 1.93 (U.S. Bureau of Census, 1953:1-100). In other words, breaking the data down by sex, we still find a rise in relative nonwhite unemployment during this period.

One can see the effects of gender differences in Oehler's Table 2 and footnote 2. She asserts in the text that differences in employment levels are not significant between blacks and whites as shown in Table 2, and that this fact remains true for males only (fn. 2). Yet the data presented in the footnote, indicating a clear rise in black male disadvantage relative to white males, reinforce the idea that we ought to keep the genders separate.

2. Gainful Employment

Oehler makes a second methodological criticism: that I combine "not gainfully employed" statistics with unemployment statistics in a single data set. She proceeds by drawing a distinction between these two types of data. I have two answers to this charge. First of all, I was fully aware of this problem. As I state in my paper (Bonacich, 1976:34):

Unemployment statistics as currently defined were not collected prior to 1940; however, earlier censuses computed the proportion of the population which was gainfully employed. The comple-

1961	2.07	2.25	1.82				

Source: U.S. Bureau of Labor Statistics, 1975:146.

ment of this figure gives us not only the proportion unemployed (defined as persons in the labor force who are out of work) but also those who have not entered the labor force. As a measure of unemployment, it has the advantage of not omitting hidden unemployment, and disadvantage of including those who would genuinely not be part of the labor force (such as students and the independently wealthy).

I used these data, not to mislead anyone, but to check the assertion by Killingsworth by trying to look at pre-1930 trends. On doing so I found a morass of confusion regarding measures of unemployment. I presented the figures on non-gainful employment from 1910 to 1930 mainly to show that more black males were working than whites, and that this was not just an artifact of differences in regional concentration between blacks and whites, which may have been subject to different economic conditions.

Second, Oehler assumes that I concluded that a shift in the ratios occurred during the 1930s because I combined the gainful employment data for 1910 to 1930 with unemployment data from 1940 on. Here she is quite mistaken. I based this conclusion on the findings of Killingsworth which include 1930 and specifically assert that a shift occurred in that decade. I never intended that the two data sets should be combined, nor is there a table which combines them.

Oehler's Table 2, in contrast, is guilty of some of the very things she charges me with. Here she combines two different data sets in one table. There are two problems with the table. First, the years 1910 and 1920 measure blacks only under "Black," while the years 1930 to 1970 include all nonwhites. Second, and more important, she uses the concept *gainful employment* as measured by the 1910 and 1920 censuses, but uses *employment* (or more precisely its reciprocal, i.e., unemployment

plus nonparticipation in the labor force) for the later decades. As stated in *Historical Statistics* (U.S. Bureau of Census, 1975:124):

The gainful worker concept differs radically from current labor force concepts. . . . The primary purpose of the gainful worker statistics was a count of occupations. The data were based on a question relating to occupational status and not to employment status as currently defined. . . . The question as posed by the enumerator made no reference to time. The response thus varied substantially with the individual. Many persons who were retired or permanently disabled and who had not worked for some time reported their former line of work and were counted as gainful workers. On the other hand, many employed persons did not enter themselves as gainful workers, because they considered themselves as students or housewives and their current employment as only temporary.

Thus, Oehler combines two noncomparable data sets in one table in order to speak of trends.

3. Timing of Shifts

As to the substantive charge, in her penultimate paragraph, Oehler recognizes that there was indeed a shift from blacks being more employed than whites, and that the ratio reached 1.0 during the thirties. She also points out that the largest jump in the ratio emerged in 1950, and concludes: "It appears, then, that an attempt to explain the relative increase in black unemployment would have to seek historical explanations in the 1940s rather than in the 1930s as Bonacich argues."

To this I can only respond that Oehler misread my article. I pointed out that the New Deal led to certain short-term effects, which equalized the price of labor, and enhanced black and white worker solidarity, but that, *in the long run*, capital was able to counter this by

internal relocation, automation, and relocation overseas. As I stated:

Black labor has been by-passed for machines and other cheap labor groups, here and abroad, creating a class of hard-core unemployed in the ghettos. This reality took a while to emerge after the New Deal and only became full-blown in the mid-1950s when black unemployment reached its current two-to-one ratio. (Bonacich, 1976:45)

Her misreading seems to arise from a confusion between two kinds of shifts. First, there was the shift from a white lead in unemployment to a black lead, in the 1930s, when the ratio passed 1.0. The second shift is the emergence of the 2.0 black to white ratio in the 1950s. She seems to think that I am only talking about the first when, in reality, the paper attempts to explain the entire sequence.

In conclusion, since Oehler essentially agrees that there was a shift in unemployment ratios, and that the timing corresponds to Killingsworth's (and my) description of it, her assertion that I build an "elaborate historical

analysis . . . based upon inappropriate use of census data" is unfounded.

MANUSCRIPTS FOR THE ASA ROSE SOCIOLOGY SERIES

Manuscripts (100 to 300 typed pages) are solicited for publication in the *ASA Arnold and Caroline Rose Monograph Series*. The Series welcomes a variety of types of sociological work—qualitative or quantitative empirical studies, and theoretical or methodological treatises. An author should submit three copies of a manuscript for consideration to the Series Editor, Professor Robin M. Williams, Jr., Department of Sociology, Cornell University, Ithaca, New York 14853.

AMERICAN SOCIOLOGICAL REVIEW

MAKING IT IN AMERICA: DIFFERENCES BETWEEN EMINENT BLACKS AND WHITE ETHNIC GROUPS*

STANLEY LIEBERSON AND DONNA K. CARTER

University of Arizona

American Sociological Review 1979, Vol. 44 (June):347-366

Blacks and five white groups are compared in terms of their rates of inclusion in *Who's Who* between 1924 and 1974. Of the groups considered, only the English exceed the national average through the end of World War II, although the other groups began to move up during this period. Jews have moved sharply ahead of the English since then, Scandinavians are now close to the English, and Italians and Slavs have increased sharply. The black rate is lowest of all, and did not move up until after World War II. There is evidence of increased assimilation between the white groups, with their sources of eminence becoming increasingly similar. However, there were and are sharp differences between blacks and whites in the pathways to national eminence. A detailed examination of the sources of each group's national prominence provides powerful clues to the differences between the forces affecting blacks and the new immigrants from South-Central-Eastern Europe, as well as between the newer and older white groups in the country. Although some immigrants with worldwide reputations were admitted, the role of immigration in generating nationally prominent Americans is misunderstood. Black sources of national eminence have shifted radically since World War II from the patterns found in 1924 or 1944.

The hardships encountered by blacks and the "new" Europeans who arrived in sizable numbers after 1880 from South, Central, and Eastern Europe, are well-known and widely documented. In this paper we are concerned, however, with the small numbers from each group who were exceptionally successful, who by some criteria might be said to have "made it" in a realm admired by Americans generally. This is a study of the representation in *Who's Who in America* of six groups: blacks; three new European groups—Italians, Slavs, and Jews; and two old European categories—the English and Scandinavians.¹ It uses three different directories (Marquis, 1924; 1944; 1974) to

cover the 50-year span between 1924 and 1974.

A study of the highly prominent members of each group asks questions not only about these people themselves but about the nature of the group's position. To be sure, prominence is not a trivial matter in itself because some of these people possess great wealth, or are in powerful political positions, or occupy central intellectual roles, or become popular models who affect others in their own group and serve as well as symbols of the group for outsiders. Positions of prominence can influence later developments for the group. Beyond this, however, differences in rates of ethnic prominence, the channels through which success is achieved, and their changes during the past half century tell us much about the entire group and the forces impinging upon it.

This is not the first study of racial or ethnic rates in *Who's Who*; witness the important work of Bardolph (1957a; 1957b) on blacks between 1936 and 1955

* Address all communications to: Stanley Lieberman; Department of Sociology; University of Arizona; Tucson, AZ 85721.

¹ The Slavic and Scandinavian categories are broader than one would ideally prefer since they cover populations in the United States normally considered separately, for example, Poles, Finns, Swedes, etc.

or the somewhat encyclopædic approach of Weyl (1966) to white rates of eminence. Moreover, there is the early effort of Woods (1914) to show that the new Europeans were inferior to the older American white stocks because at that time the former had far lower rates of national eminence. Nevertheless, to our knowledge, this is the first study which rigorously compares blacks and these white groups in terms of the career lines which have led to national eminence and provides a systematic measurement of the group rates of eminence over time, recognizing the changing population composition of the nation. It is our belief that a study of the prominent within each group, as arbitrary as such a definition may be with the use of these directories, can throw a distinctive and important light on race and ethnic relations in this country, present and past.

DATA AND METHODS

The basic data sources are the 1924-25, 1944-45, and 1974-75 editions of *Who's Who in America*, a standard reference work which attempts to list eminent living Americans. There are serious limitations and difficulties in using these volumes: the criteria for inclusion may not be consistent over time (as will be shown, there is evidence that they are not); ethnic or racial membership could affect the possibility of inclusion; determination of eminence within a given occupational or professional category can be arbitrary such that there is no purely objective basis for a decision. Also, it is difficult to equilibrate the various forms and ways of achieving eminence or distinction in different domains, for example, holding national office in the League of Women Voters vs. ownership of a large scrap processing operation vs. managing a minor league baseball team vs. being a crime boss, etc. All of this means that the listings obtained from *Who's Who* are of less than precise validity; on the other hand there is probably no better source for a systematic comparison of the different groups in terms of the upper end of various career paths. As Baltzell (1966:271) observes after summarizing the direc-

tory's inadequacies, it "is a nationally recognized listing of brief biographies of the leading men and women in contemporary American life. As such, it is a perfectly democratic index of high functional class position and has wide prestige." The reader should keep in mind that such terms as *prominent* and *eminent* will refer to persons listed in these directories.

It is impossible to determine ethnic origin and race by contacting each person listed in *Who's Who* because most of those listed in the earlier two volumes are no longer alive. Moreover, even for the most recent period, it would take an extremely large sample to obtain a minimally adequate number for some of the groups. A rather simple and reasonably effective procedure was adopted for the white groups. Weyl (1966:219-21) lists a set of surnames corresponding to various ethnic groups along with the number of each surname appearing on Social Security lists in mid-1956. Among Italians, for example, surnames beginning with the following are included: Caruso, Costa, Esposi, Ferrar, Marino, Romano, and Rossi.² Whenever possible, persons with these surnames listed in *Who's Who* were used to generate about 100 or so representatives of each white group for a given period. The number of necessary surnames varied over time for some groups, but this was taken into account when rates of change were computed. In other cases, the available list of leading surnames and/or the number listed in *Who's Who* was so small that it was necessary to supplement the listing with additional ethnic names from the directory of surnames edited by Smith (1973), a volume which gives the ethnic group associated with each surname. Even then, it was not always possible to reach the goal of 100 per group for each period. These additions were not included in the calculation of the prevalence rates shown in Table 1.

Obviously the surname technique has its problems, with errors of both exclusion and inclusion. To some unknown degree there are persons who are not members of

² All names that start with the specified letters are included, for example, *Costantini*, *Costanzo*, *Costanza*, as well as *Costa* alone.

Table 1. Listings in *Who's Who* per 10,000 Population

Group	Year		
	1924-25	1944-45	1974-75
Total Population	2.27	2.48	3.42
Black	.06	.07	.37
English	3.74	3.74	3.88
Italian	.09	.33	1.31
Jewish	1.59	1.97	8.39
Scandinavian	.42	1.29	3.57
Slavic	.16	.29	1.48

the ethnic group attributed to them on the basis of surname. On the other hand there are those who belong to these ethnic groups but have surnames that would not identify them as such. It is likely that the latter are subject to less discrimination and prejudice than might otherwise be faced. In more recent times, intermarriages between the groups make attribution of ethnic origin even more complex. However, one can reasonably assume that the sample in each period does approximate the patterns and behavior of eminently successful members of each ethnic group.

Surnames clearly do not form an adequate basis for determining black representation in *Who's Who*. Fortunately, blacks included in *Who's Who* were listed in Work (1925) and Guzman (1947) for both the 1924-25 and the 1944-45 periods, respectively—indeed, the 1924 and 1944 periods were selected in order to take advantage of these lists. It is not entirely clear to us how these lists were developed and hence one cannot fully guard against the possibility here too of errors of both inclusion and exclusion. No list could be found for the most recent period and it was necessary to use a different procedure because black representation in *Who's Who* since World War II is clearly of great interest. Assuming that virtually all blacks listed in the 1974-75 *Who's Who in America* are also found in their own ethnic volume, all of the listings in *Who's Who Among Black Americans, 1975-76*, edited by Matney (1976), starting with the letter A were checked against *Who's Who in America* until some 125 blacks were thus obtained. There could be errors of omission here since those not listed in Matney (1976) will have no chance of being

counted as a black listed in *Who's Who in America*, but that would be analogous to those lost through nonethnic surnames in the case of the white groups. The adequacy of such a technique can be tested for an earlier period, 1944-45, by determining how many blacks listed in *Who's Who in America* (according to Guzman, 1947) would have been included in a directory of eminent blacks published about that time (Fleming and Burckel, 1950). Only two of 72 blacks listed in *Who's Who in America* and still alive several years later were not found in the black directory. Hence, for an earlier period at least, the procedure used in 1974 worked very well. The Appendix provides a more detailed statement of the procedures used for both blacks and the white groups as well as their limitations.

The coding of occupational categories is somewhat arbitrary and approximate. This is unavoidable because some respondents have several positions at the same time or are vague about their current occupation, as opposed to earlier positions. As far as possible, we classified respondents in terms of their current dominant position. The unavoidable overlaps between some of the categories were resolved through several arbitrary rules of thumb. Except for physicians, all others employed as professors in a university or college were so classified rather than as, for example, chemists, historians, lawyers, etc. Physicians were classified as such even if they were professors of medicine or otherwise employed, whereas lawyers were classified by their most recent activity.

ETHNIC AND RACIAL INCLUSION IN *WHO'S WHO*

The proportion of Americans included in *Who's Who* has increased through the years. The first volume, for 1899-1900, listed only 1.15 persons per 10,000; and 2 and 3 per 10,000 were first reached in 1912-13 and 1954-55 respectively (figures reported in Larson, 1958:6). In 1924-25, the beginning of the 50-year span under consideration here, when the rate for all Americans was 2.27, of the groups considered here only the English reached that

level—and they exceeded it by a sizable margin. Although the rate for Jews was less than half of the English, they stood out from the remaining groups, with Scandinavians, Slavs, Italians, and blacks following in that order (see Table 1). This was for the year when relatively unrestricted migration to the United States was first stopped, but even then blacks were still below the new European groups considered here.

Twenty years later, toward the end of World War II, none of the three new European groups had reached the national average, although Jews were getting closer and the other two had handsome rates of increase based on very small initial levels. Scandinavians were coming along strongly, although their rate in 1944 was still half of the national average. The English were well ahead of the groups specified here as well as the national average. Blacks were still essentially unchanged from their level 20 years ago.

By 1974–75 there were some extraordinary changes. Americans of English origin had gained somewhat over their level in 1944, but it was not enough to make up for the much higher rate of inclusion in *Who's Who*, so that their rate, 3.88, was only slightly above the national average of 3.42. Jews gained at an incredible pace after World War II, with a *Who's Who* rate in 1974 of 8.39, about 2.5 times greater than the national average. Scandinavians were now also enjoying a rate slightly in excess of the national average (given the crude nature of the figures, it would be safest to say that they were about at the national level). Both the Slavs and Italians were still well below the national level, but had clearly moved ahead during the 30 years, increasing in the magnitude of four and five times, respectively, over their 1944 levels. The black rate had also quintupled during this span, reaching .37, which was still about one-tenth of the national average. Starting with such a low base in 1924 and having barely made any progress through World War II in reaching national eminence, this sharp postwar jump still left them far behind.

One should keep in mind certain technical factors in appraising these different rates. Larger groups are less likely to de-

viate greatly from the national average simply because of the "part-whole effect." This is particularly important for the English who are an important segment of the national population. Further, one should bear in mind that a variety of ethnic groups whose behavior has a substantial bearing on the national averages are not included in this analysis; particularly important are other groups from the British Isles—the Scottish, Welsh, and the Irish—and Germans as well as many other groups. Moreover, continuing processes of intermarriage, name changing, and the like are affecting the meaning of each surname rate over time.

Nevertheless, the figures in Table 1 show how truly dramatic were the changes in the position of various white ethnic groups in the post-World War II period. It is not clear whether the recent rapid rates of change are a continuation of shifts that had begun to occur in the period between the two world wars rather than being uniquely stimulated by events surrounding the end of the second war. This is an important issue that, in itself, merits separate consideration elsewhere. The eminence pattern for blacks is striking because (1) it was initially somewhat lower than the new European groups; (2) there was no sign of any true increase between 1924 and 1944, a period when the absolute gains were modest for Italians and Slavs, but were nevertheless relatively sizable compared with their small initial levels; and (3) there are now signs of change for blacks. Their rates are presently in excess of the levels reached by Italians and Slavs 30 years ago, albeit well below the rates observed for Scandinavians and Jews 50 years ago. Their increase is probably not due to a special effort to include blacks. Among 25 black colleges sampled, the presidents of 11 were included in *Who's Who* in 1974 compared with nine in 1944—a minor temporal difference.

OCCUPATIONS

The groups vary not only in their rates of eminence but also in the occupational routes through which such a distinction is achieved. In comparing these pathways to prominence, bear in mind that the chance

of making it into *Who's Who* varies by occupation and hence the directory distribution does not reflect the frequency with which such occupations are pursued by members of an ethnic group. In addition, the chance of making it in *Who's Who* for persons holding a given occupation probably varies between ethnic groups. As a consequence, no inferences can be made about the underlying occupational distribution of the population based on the eminent members of the group reported in *Who's Who*.

Differences among groups in the occupational patterns of their eminent members can be summarized with the index of dissimilarity. The index ranges from zero (if the groups being compared have identical occupational distributions) to 100 (if the occupational distributions are so different for the two groups that no occupation is held by both). Unfortunately, the number of cases is rather small, particularly for some of the groups in the earlier years, and the number of occupational categories is relatively large. The indexes are computed on the basis of all of the occupational categories—not just those listed separately later in Table 4. These factors tend to introduce a serious sampling problem in the measure and hence small differences between indexes cannot be taken seriously (see Cortese et al., 1976). Bear in mind, too, that the index of dissimilarity does not rank order the occupations and hence differences in degree between occupations are not taken into account (see Lieberman, 1975).

Initially, the differences between blacks and the various white groups were not that much greater than the indexes found between the white groups. The indexes were relatively high in 1924–25 but in a rather narrow range, with the average index of dissimilarity ranging on the low side from 46 and 48, respectively, for Scandinavian and English comparisons with other groups. Blacks were towards the high end of the range, 62, but were only slightly more than the average for Slavs, 61, and actually slightly less than Italians, 64 (see Table 2). Jews occupied an intermediate position, with an average index of 52 against each of the other groups. With one major exception, the groups have become

Table 2. Indexes of Dissimilarity

Group (and Comparison)	Year		
	1924–25	1944–45	1974–75

vs. white groups	46	36	22
Slavic			
vs. all groups	61	35	29
vs. white groups	58	31	22

more alike over time in the occupational distribution of their eminent members. Observe in Table 2 how the average index between white groups progressively declined such that by 1974–75 they ranged between 22 and 31. Blacks, on the other hand, had an average index of 54 from these white groups. The decline in black-white differences during the first 20 years was not as sizable and, moreover, in the recent period there was an actual increase. Whereas the occupations of white ethnic group members making it in *Who's Who* have become more alike, the distribution for blacks remained far more distinctive.

These changes reflect some surprising processes. In the earliest period, blacks exceeded all other groups in the extent to which they were concentrated into a small number of occupations (see the Gini concentration ratios in Table 3) such that 70% of all blacks in *Who's Who* were either

Table 3. Gini Concentration Ratios

Group	Year		
	1924–25	1944–45	1974–75
Black	.8434	.8173	.6682
English	.6541	.6767	.7889
Italian	.7799	.6985	.7430
Jewish	.6525	.7034	.8289
Scandinavian	.5520	.6767	.7947
Slavic	.8130	.6487	.8089

Based on cumulative proportions of occupational categories vs. persons in each category—with the latter arrayed from high to low.

religious figures (47.5%) or college professors and administrators (22.5%). By contrast, the largest two occupations for Jews held only about 30% of that group's listings in *Who's Who* (lawyers and physicians, 17 and 14%, respectively). The figures were also much lower for the largest two occupations among Scandinavians, 32% (college professors and administrators, and religious leaders); English, 40% (college professors and journalists); Italians, 40% (singers and musicians, and bankers or authors).³ Only the Slavs were close to the black concentration ratio, .81, with 62% in their largest two categories: college professors, and singers or musicians.

The situation was rather different by 1974-75, with the white groups now far more concentrated than they had been, and blacks having the lowest Gini index of any of the groups. This combination of greater white concentration coupled with increased similarity in the locus of their concentration is what generated the lower indexes of dissimilarity described above. For example, the single largest source of eminence for all of the groups, blacks included, is college professors and administrators. But there is wide variation among the groups in the degree of concentration; 19% of eminent blacks were in this category whereas 26% of Italians, about a third of English and Scandinavians (34 and 38%, respectively), and about 45% of Slavs and Jews were so concentrated.

These figures indicate that the various white groups are assimilating or merging as far as the ways in which they make it to *Who's Who*, but thus far blacks are left out. In earlier periods the white groups as well as blacks had distinctive occupational routes to prominence. The black-white ethnic group differences are now far greater than the differences among the white groups. The black group is now more distinctive than ever in the routes by which they enter *Who's Who*.

SPECIFIC BLACK OCCUPATIONS

The specific occupations of blacks and whites listed in *Who's Who* provide a

powerful clue to the broader societal forces differentially affecting these groups. Particularly revealing are both the positions through which members of the six groups attained such a distinction in 1924 as well as the changes that have occurred since then in their pathways to distinction. Because of the small numbers involved, concern with issues of sample size and reliability must be relaxed more than we would prefer, but in our estimation the occupational patterns among these small subpopulations shed light on certain facets of race and ethnic relations in this nation that would otherwise not be possible. This section focuses on black occupations, with a secondary concern given to comparisons with the white ethnic groups. The opposite emphasis is taken in the succeeding section.

1924-25. Nearly half of the 80 blacks found in *Who's Who* in 1924-25 were there because of their position in organized religion. Of the 38 included, 19 were either bishops of the African Methodist Episcopal Church or otherwise affiliated with the largest exclusively black church body in the nation, and ten were bishops of the Methodist Episcopal Church, with smaller numbers of Baptists and others represented (including two bishops of unspecified churches). By contrast, there were no Italian or Slavic religious leaders found in the very small samples of those groups in this period and religious leaders made up relatively small percentages of the English, Scandinavian, and Jewish groups' 1924 representation (respectively, 5, 9, and 11%). Although blacks had this exceptional concentration in the religious path to *Who's Who*, their concentration as college professors and administrators, 23%, is not unusually low when compared with the English (25%) and Scandinavians (23%), and is considerably greater than for Jews and Italians (12 and 8%, respectively). It is only among Slavs that we find a much larger component making it through a college or university affiliation, 38%.

Both of the major sources of black eminence 50 years ago were segregated institutions in which whites did not compete, but in which at least some minimal recognition on the national plane could be obtained. These two categories, colleges

³ All the specific occupational categories used are listed in Table 4.

and religion, incorporated 70% of all blacks in *Who's Who*. There was a massive difference between blacks and the new Europeans at the very start of this period. The ten Slavic college professors and administrators were almost without exception affiliated with major, nationally prominent institutions: Chicago, Harvard, Illinois, Iowa State, Michigan, Minnesota, Northwestern, Wisconsin, and Yale (2). By contrast, every black in this category was affiliated with a black institution, located outside the national mainstream of the white-dominated society.

The next largest category for blacks in 1924–25 was authors, of which there were seven (roughly 9% of all blacks in *Who's Who*). Judging by title, and reputation in some cases, there is evidence that most of these authors were writing about blacks, but probably at least some were reaching a broader audience in the nation rather than a segregated one. All seven were found in the Burke and Howe (1943) reference on American authors. It is, of course, quite common for authors to write about their own experiences and, in this case, writing about the black experience meant an opportunity to develop a larger audience and make it outside the segregated market existing for many other blacks. Doubtlessly, the remainder of blacks in *Who's Who* in 1924 includes some who also served a segregated population.

1944–45. Several major changes occurred for both blacks and whites during these 20 years. Religion was no longer a major means for entrance into *Who's Who* for blacks, with only 8% of those listed now in this category. Although one may speculate that this change reflects an increasing secularization (Bardolph, 1957a:185), we believe that two other factors also account for this shift. Notwithstanding claims to the contrary (Marquis, 1944:xi), by 1944 A.M.E. bishops were de-emphasized as a source of listings. Second, the merger in 1939 of several Methodist organizations led to most blacks being placed into one jurisdiction (see Guzman, 1947:124). Therefore, although a sizable proportion of these officials were included in the 1944–45 *Who's Who*, the absolute number was no longer as great as it had been.

Taking up the slack was the academic

world; its proportion of eminent blacks more than doubled during this period, an enormous jump which was not shared by the other groups. In 1944–45, four of the white groups ranged from 20 to 21% in the fraction of its eminent people associated with colleges and universities, with the Scandinavians reaching 32%. By contrast, 52% of all listed blacks were in this category. Many of these black academics boasted excellent institutional credentials. The highest degree for nine of the 44 was from Columbia, eight were from Harvard, seven were from Chicago, and there were several other nationally prominent institutions represented in smaller numbers. Again, as far as we could tell, virtually all of the blacks were affiliated with predominantly black institutions. By contrast, the 16 academics of Italian origin included three appointments at Harvard, and one each at Cornell, U.C.L.A., Columbia, California, and Chicago. Although the institutional affiliations were not as uniformly impressive as the Slavs listed in 1924, clearly we can see a great difference from the black experience.

A new category, singers and musicians, became important by 1944. Whereas this had been the source of two prominent blacks in the first period, there were now eight in this class (9.5% of the eminent blacks in 1944–45). For the most part, these blacks were in the classical tradition; in addition to contralto Marian Anderson and singer-actor Paul Robeson, there were several other concert singers and composers of classical music. W. C. Handy, composer of a number of important blues and a band leader, to our knowledge was the only exception. No English or Scandinavians in our sample made it into *Who's Who* through music (obviously this would not have been the case if the entire population had been covered); and 5% of Jews made it through this route, but music in 1944 was an even more important route for Slavs and Italians (15 and 16%, respectively) than it had been for blacks. A more thorough comparison is made later in the paper.

The author category was again important for blacks, amounting to 8% of all their listings, far greater than the figure for any other group. Again, the list included a number who were writing about black ex-

periences, but for a larger audience than simply blacks, for example, Langston Hughes (see Bardolph, 1957b:268). Both music and writing provided paths to prominence which were not based exclusively on a black audience or requiring approval exclusively from blacks. Both activities are relatively less "institutionalized" or rigidly structured in their career lines than are many others, for example, reaching the top in a large corporation. Hence, there may have been relatively less difficulty in these domains than in other more formal systems. No other category captured as much as 5% of the black listings, other than the four journalists who barely made the cut-off. There were only two black doctors and one lawyer in the 1944-45 listings. In 1924-25, there were no black businessmen or bankers listed and this was the case again except for one black banker.

1974-75. The post-World War II period has witnessed some significant changes in black occupational roles among those in *Who's Who*. As noted earlier, colleges and universities were the most important passageway into eminence for all of the groups, but it became relatively less so for blacks. In thirty years since the end of World War II a massive shift sent the black figure plummeting from an exceptionally high 52% in 1944 to an exceptionally low 19%. This change in itself was sufficient to mean a massive redistribution. Of those in this category, however, about a third are affiliated with institutions that are not predominantly black. So, although relatively less important to blacks than it had been as an entry into *Who's Who*, academia now functions for the first time on the national stage rather than as a segregated institution. Of course, the integration of academic institutions and the opening of other opportunities are not uncorrelated but probably reflect the greater "muscle," awareness, and governmental pressures experienced in recent years. Bear in mind that the number of eminent black academics actually increased at a faster rate than the total black population, but its growth was not as great as that experienced by other sources of eminence (see the discussion of Jews in government below).

Sports and entertainment are both major sources of national distinction for blacks in a way that is unmatched for any other group. The singer-musician and athlete categories are the second and third most important sources of blacks in *Who's Who* in 1974-75, 15 and 14%, respectively. These rates, to use a show business term, are colossal when compared with the white groups. Singers and musicians are 3% or less of the white listings, except for Italians, and athletes are not more than 4%. Bear in mind these figures do not mean that more musicians or athletes are black than white, rather it means that these areas are far more important sources of eminence among blacks than among any of the white groups under consideration. Entertainment, moreover, is a major way of achieving such prominence within a national community rather than on a segregated basis. As we have seen, much of the earlier routes of eminence for blacks meant competing with other blacks and rising to the top within the black community, but with whites absent as either competitors or members of the "audience" of peers. This, of course, was not by black choice but by restriction. Sports and entertainment are therefore striking because they have become major avenues, to a degree unrivaled, for achieving national prominence with adulation from both whites and blacks in competition with both whites and blacks.

The procedures used in this study may specially underestimate the role of singers, musicians, actors, and other popular entertainers among the various white ethnic groups. This is because there is a tendency for such persons to change surnames, particularly in the direction of anglicizing them. There may have been less of such a tendency in the more "cultural" forms of entertainment such as, for example, the conducting, playing, and singing of classical music. Keeping this problem in mind, the singer-musician pattern for the white groups seems to be moving in the opposite direction from blacks. Such pursuits were not important sources of eminence for the English or Scandinavian groups despite the surname bias in favor of the former. No whites of English origin were included in the samples for

any of the three periods; and the 5% for Scandinavians in 1924-25 (based on three classic artists, two singers with the Metropolitan Opera, and a violinist-conductor-instructor), declined after that. For Jews, it has been a relatively unimportant source as well, ranging from 3 to 5%. Again bear in mind the problem of surname changes in the direction away from South-Central-Eastern European identity, particularly where popular forms of entertainment are concerned. Music had been an extremely important factor for both the Italian and Slavic groups earlier in the century and we will later consider some of the differences between these groups and blacks.

It is impossible to say if an analogous process occurred in athletics such that its role as a source of fame among blacks increased at the same time as it declined among some of the white ethnic groups. This is because neither the 1924 nor the 1944 editions of *Who's Who* included any athletes in the group samples. Further examination indicates that *Who's Who* has only recently increased its willingness to include athletes. Hence the early periods are not really comparable and nothing more can be made of this issue. This inference is based on a special test of the listings. The baseball stars voted Most Valuable Player (MVP) in each of the two major leagues between 1937 and 1940 were checked in the 1944-45 *Who's Who* as well as the National Football League's MVP and leading scorers for 1938 through 1940 (this allowed the directory a few years lag time to include them). None of the eight baseball stars were listed in *Who's Who*, despite the fact that the list included Joe DiMaggio, Jimmy Foxx, Hank Greenberg, Bucky Walters, and the like. By contrast, six of the eight baseball MVPs selected during several years before the 1974 *Who's Who* are found in that directory. Likewise, whereas none of the six star professional football players were included in the earlier *Who's Who*, four of six recent choices were found in the current directory. Hence, the shift in listing policies makes it difficult to compare earlier trends.⁴

⁴ This also means that for some purposes it would

Although religion declined even further in 1974 from its incredible role in 1924, it was still a more important factor for blacks than any of the other groups, with 6% so represented vs. 1 to 3% among the others. Likewise, authors are still relatively prominent among blacks in the current period; small in number, 4% of the black sample, this is greater than the figure for any other population.

Business alone is the second most common source of eminence for all of the white groups, but for blacks it is the fifth most important pathway into *Who's Who*, accounting for only 6% of blacks as contrasted with 18 to 24% of the whites. Medicine and law are also important pathways into *Who's Who*, ranging from third to sixth place among each of the white groups, but are fourteenth and fifteenth, respectively, for blacks. Only two practicing black attorneys are included in our sample of 125 blacks, whereas this category ranged from 10 and 9% of Jews and English to 4% for Italians and Scandinavians. Eminent blacks are now more likely to originate from the realms of business and banking than before, 8%, as opposed to none in the first period and only one black in 1944. But bear in mind that this is still well below the figures for the white groups, which range between 21 and 29%.

Government and politics has become an important source of black eminence in *Who's Who*. This category combines such diverse and relatively infrequent listings as congressmen, military officers, judges, governors, diplomats, public officials, mayors, and the like. In 1924-25, only one black was so classified; in 1944-45, 7% of all blacks were in this domain and currently government and politics accounts for 13% of all black listings. This steady increase has moved blacks from the lowest level in the first period, when government and politics was the source of from 8

be desirable to recompute the distribution for 1974-75 and exclude athletes for blacks and other groups in order to examine the data over time on a comparable basis. However, it is probably the case that there are many other shifts in the overall distribution of occupations listed in *Who's Who* which reflect changes in their numerical frequency and their perceived importance.

to 20% of the listings for the other groups, to the second highest role in the current, with Scandinavians exceeding blacks by only 1%. Although government obviously plays an increasingly important role in the national life, witness the increase in the proportion of the GNP that it consumes (Lieberson, 1971); surprisingly the government plays a decreasing role since World War II as an entry into *Who's Who*. A government linkage existed for 22% of the English listed in the 1944-45 directory, whereas it was 9% in 1974, a figure which is actually lower than it had been in 1924. The greatest role of government for both Scandinavian and Jewish listings had been in 1924-25, with figures for both groups declining in the succeeding two periods. Italians and Slavs both experienced declines during the most recent span, from 15 to 6% and from 14 to 7%, respectively. These drops were also greater than the gains occurring between 1924 and 1944. Hence government contributes a relatively smaller proportion for all five of the white groups than it ever did before, whereas the opposite is the case for blacks.

Again, these findings do not necessarily mean that the white groups are massively less active in government than they used to be, although clearly blacks have captured a more important position than ever held before and obviously such gains must come at the expense of whites (although not necessarily the ones under study here). Nevertheless much of the shift occurs because the role of other activities has increased more rapidly and more members of some of the groups are making it into *Who's Who* through different routes. For example, government has played a relatively smaller role for Jews than for any other of the white groups under consideration. In 1924-25, it was the source of 8% of the group's listings in the directory, the same level as for Italians and well above the miniscule black representation. In 1944-45, the percentage among Jews had declined to 6, lower than any of the other groups including blacks, and in 1974-75 government was the primary affiliation of only 4% of the Jews in *Who's Who*. But bear in mind that the prevalence of Jews in *Who's Who* had in-

creased from an estimated 1.59 per 10,000 in 1924 to 1.97 in 1944 and 8.39 in 1974 (Table 1). Multiplying these rates by the proportion of those listed in *Who's Who* with political or governmental affiliations in each period, one estimates that the rate of representation in *Who's Who* from the governmental source dropped slightly from .12 per 10,000 in 1924 to .11 in 1944 and then increased to .32 per 10,000 in 1974-75.⁵ In other words, the actual prevalence of Jews in *Who's Who* through politics has gone up even though the proportion of Jews in *Who's Who* through politics declined. Obviously with such small numbers one cannot take these figures too seriously because of enormous sampling errors, but the figures do serve to illustrate how changes in the relative predominance of an occupation in the *Who's Who* listings for a given ethnic or racial group do not necessarily mean similar changes in the proportion of members of a given group reaching the directory through the specified occupation.

In general, there have been some radical changes among eminent blacks in the United States. Initially it was possible to make it almost solely through some form of segregated activity, for example, black colleges or religious organizations. This is no longer the case, but segregated sources of esteem are still important. Granted that blacks are disproportionately active in sports and probably entertainment, part of the reason for their high showing in such activities is their extremely low showing in many other sources of white entrance into national prominence. If the 1974-75 black eminence ratio was the same as it is for the total population, 3.42 instead of .37 per 10,000, and if all of the black gains were to come from nonentertainment sources, then singer-musicians would comprise .0164 of all eminent blacks instead of .0152 ($.37/3.42 \times .0152$) and athletes would be .0156 instead of .0144 ($.37/3.42 \times .0144$). In other words, if we artificially assume no discrimination in sports and entertainment presently and hence that their entry is as great as it ever will be, then black parity with the remain-

⁵ Based on the following multiplications: $(.0758)(1.59) = .12$; $(.0560)(1.97) = .11$; $(.0387)(8.39) = .32$.

der of the nation in the achievement of eminence would mean a massive drop in the relative importance of these activities. Nevertheless, at present sports and show business do provide blacks with eminence on a truly national plane with a white audience included and in competition with whites. Looking at the past, this is an important factor insofar as much of the earlier achievers were restricted to a black professional audience and could not compete directly with whites. The recent changes among black college professors also reflect the movement into a broader form of eminence. To be sure, virtually no accomplished scholar in the various disciplines achieves the kind of popular fame that is possible for sports and entertainment figures, but within a more restricted audience of professional peers the same process of competition across racial lines and with a mixed audience exists.

ETHNIC OCCUPATIONS

Given these observations on black sources of success, the issue naturally arises of how different this black pattern is from those experienced by the white groups. Of particular interest are the new groups who first began their migration to the United States in sizable numbers at the tail end of the last century—Italians, Slavs, and Jews.⁶ Part of the answer has been touched on earlier in our discussion of blacks, but some added considerations are appropriate here.

Slavs in 1924 were most concentrated in the university world, with the second most important source of eminence being singers and musicians. As noted earlier, the college activities were all confined to nationally recognized institutions of the highest quality. The six Slavic musicians are all in the classical domain, including two members of the Boston Symphonic Orchestra, a composer who also served as president of the Chicago Music School, a concert violinist, an operatic tenor, and a pianist-composer. Of these six, five were

born outside the United States. Observe that the white ethnic groups enjoyed two special advantages over blacks. First, their distinctive ethnic cultural concerns fit in nicely with the high culture supported by the nation's elite. There was no problem or difficulty including such outstanding artists in *Who's Who* since they obviously added great distinction and their accomplishments would also be fully appreciated outside the United States. For blacks, by contrast, their distinctive artistic accomplishments, such as in music, were not yet considered noteworthy or in any way comparable in accomplishment to the classics. As a consequence a form of esteem and national recognition was not possible for blacks whereas it was an immediate entry for those members of the new European groups who excelled. The second point is that five of the six Slavic musicians mentioned in 1924 were foreign-born. Unlike the black population, the new Europeans could be aided through the migration of distinguished ethnic compatriots from the homeland. (The exact role of the immigrant will be analyzed later.)

It is clear that at the very outset the Slavic group making it into *Who's Who*, although small in number and representing a low success rate at that time, was making it through national as opposed to segregated pathways. To be sure, music represented an ethnic pathway in some respects, but it represented a pathway that the larger white society had defined as admirable and respectable, classical as opposed to merely popular. It was part of the European civilization and culture that was a mark of cultivation to enjoy and respect; in short it was "legitimate."

A somewhat similar pattern is found for Italians in 1924–25. The largest single category is singer-musician. Eight of the nine Italians so listed are affiliated with operas in either a singing or administrative role and the remaining one Italian is a harpist and composer. All but one of the eight were foreign-born. Hence the comments about Slavic musical figures applies here too. By contrast, most blacks making it into *Who's Who* through music in 1944 were in the classical tradition. It was not until the post-World War II period that

⁶ Bear in mind that not all Jews are new Europeans. One does not know how much of a role Jews from Germany and other older sources are playing in the early listings.

music closer to black folk traditions became a source of entry.

Jews had a different set of major pathways into the 1924-25 *Who's Who*. Although the university world in 1974-75 was to become the single most important source of eminence for Jews and more important to them than any other group, in this early period the percentage of Jews so concentrated was smaller than among all other groups except Italians. The figure for Jews was 12%, compared with 38 for Slavs, 25 for the English, and 23 for both Scandinavians and blacks. The low percentage for Jews is surprising, but easily explained. The reader will recall from Table 1 that in 1924-25 the prevalence of Jews in *Who's Who*, although distinctly below the frequency for the English, is still far greater on a per capita basis than among the remaining groups. Accordingly, if one multiplies the prevalence figures in Table 1 by the proportion shown in Table 4 who are academics, it turns out that Jews have a higher frequency of making it into *Who's Who* as academics than all but the English ethnic group in 1924. In other words, the importance of academia is low for Jews relative to other occupational pathways in 1924 when compared with other ethnic groups, but not in absolute terms. Nevertheless this was still the third most important source of eminence then, with a list of institutions less distinguished than the Slavic one but still including faculty at Columbia, Johns Hopkins, Pittsburgh, and Wisconsin.

Law and medicine were the two most important sources of eminence for Jews in 1924. Seventeen percent of listed Jews were lawyers (the next highest figure for the remaining groups was 7) and 14% were doctors (as opposed to 8% for the next highest). As for the nine physicians listed, as is typically the case for the other groups, many held medical school appointments. This is to be expected since the average physician, specialist or not, is unlikely to be listed in the directory. There were several other important sources of prominent Jews in that period. Religion amounted to 11% of the eminent Jews, but this figure was to go progressively downward as Jews expanded into other domains, with religion accounting

for 1% of all eminent Jews in 1974-75. The only other source contributing 10% or more of Jews in 1924 was the combined categories of business and banking (six were sampled in business and one in banking). The combined percentage is higher than for most of the other groups in 1924.

By 1974 there were some radical changes for these new European groups, with the most important and basic one being a shift towards similarity in their occupational patterns. As noted above, Jews occupy an exceptionally high concentration in academic positions, but law, medicine, and business have all declined as exceptional routes for the group when compared with other white populations. Between 1924 and 1944, when blacks increased from 3 to 10% in music, the figure for Italians halved and likewise went down substantially for Slavs. Both groups went down further by 1974-75; indeed singers and musicians are now only 2% of the listed Slavs but they are still an important, albeit diminished, 8% for Italians. Blacks, of course, had skyrocketed during this same span. It is interesting to note that both groups shifted towards popular music in this period, but much more so for blacks.

BIRTHPLACE FACTORS

It is well-known that many eminent Europeans migrated to the United States, not only as refugees during the 1930s, of which there were an extraordinary number (see Fermi, 1971), but also in earlier decades as well. Could it be that these immigrants were a specially important factor in the groups' representation in *Who's Who* as well as the increases enjoyed by them? The answer is not immediately clear because the vast bulk of immigrants from South-Central-Eastern Europe during the heyday of migration possessed minimal education, little in the way of financial resources or occupational skills, and were often unable to speak English—hardly the ideal starting point for attaining a distinguished career. It may be that the dramatic and exceptional contributions of such immigrants as Marc Chagall, Franz Alexander, Bruno Bettelheim, Bela Bartok, George Gamow,

¹ This is a combination of separate categories that were later combined, after all indexes were computed, and include: public officials, congressmen, military personnel, judges, governors, diplomats, public service employees, mayors, and United Nations officials.

² These include the following occupations for each group as follows:

Rudolph Carnap, George Szell, Albert Einstein, Igor Stravinsky, Paul Tillich, Enrico Fermi, Jacques Lipchitz, and John Von Neumann (all taken from the list of photographs in Fermi, 1971) was more than overbalanced proportionately by the great mass of migrants.

Shown in Table 5 is the foreign-born component in each group's listings. As one might expect, this component has generally declined over time—the exceptions may be in part due to the sampling variations that occur with such small numbers. The foreign-born accounted for a sizable part of the Italian, Jewish, Scandinavian, and Slavic groups' listings 50 years ago, ranging from more than a quarter of the Scandinavians to nearly half of the Slavs. There was a sharp drop-off in the role of the foreign-born between 1944 and 1974 for these four groups. It may well be that the less rapid decline for Jews and Slavs between 1924 and 1944 is due to the specially significant refugee movement in the period leading to World War II.

It is necessary to compare the immigrant contribution to *Who's Who* with their proportion of residents in the nation. There are some obvious difficulties, not the least of which is that the census delineated ethnic origin only for the immigrant and second generations.⁷ Using 1940 census data which cross tabulate generation (foreign-born, or second generation) with age, the proportion of *Who's Who* listings that might be expected to be foreign-born (given the age distribution in *Who's Who* and the aforementioned cross tabulations) was determined for the Italian, Slavic, and Scandinavian groups.⁸ This cannot be done for Jews because there is no simple correspondence between that group and some country of

Table 5. Percent Foreign-Born

Group	Year		
	1924-25	1944-45	1974-75
Black	10.00	1.19	—
English	8.00	3.00	7.50
Italian	42.31	36.00	13.60
Jewish	31.82	29.60	9.68
Scandinavian	28.57	20.00	0.80
Slavic	46.15	47.89	17.60

birth. At any rate, for each group the actual foreign birth percentage in *Who's Who* is far less than one would expect based on the age distribution of persons in the directory and the age distribution of the immigrants and second generation components of the group. If *Who's Who* in 1944 had the same proportion of immigrants as was found among those in the age groups represented in that directory, about 72% of the Slavs would have been foreign-born instead of 48. Likewise, 20% of the Scandinavians in *Who's Who* in 1944 are foreign-born, but one would expect this to be 47% if the immigrants living in the United States were contributing their proportionate share, given their age composition and the age distribution of Scandinavians listed in *Who's Who*. Finally, although immigrants comprise a sizable 36% of the eminent Italians listed, one would expect 80% if the age distribution is standardized.

In short, the eminence rates for the immigrants were lower than those found among the American-born generation. A sizable part of the recent gains in the eminence rates of the new European groups is probably due to the increases in their American-born component. Nevertheless, it is clear that the immigrants did include some world famous intellectuals, artists, and other persons of importance. Accordingly, the new Europeans did have an "ethnic legitimation" going for them that was denied to blacks, first because there were great barriers to African immigration and second because the cultural and intellectual attainments of the new Europeans could be immediately absorbed into the larger American society—witness the classical music illustrations cited earlier. Blacks did not have these "flagship" models.

⁷ Although the expected foreign-born percentage would go down if data were available for later generations, it is unlikely that it would go down that much because the bulk of these groups had not been in the country that long and, moreover, a sizable part of the third generation was probably too young in 1944 to be serious contenders for *Who's Who*.

⁸ This was based on Polish, Czech, and Yugoslavian groups combined for the Slavs (no other Slavic group data available), and Norwegians, Swedes, Danes, and Finns combined for Scandinavians. The basic data source for the necessary tabulations is U.S. Bureau of the Census, 1943.

Birthplace differences among blacks. Differences between southern- and northern-born blacks on a wide variety of characteristics have undergone considerable debate and speculation in recent years (see, for example, Long and Heltman, 1975; Lieberman and Wilkinson, 1976; Lieberman, 1978). There is certainly some grounds for considering southern-born blacks in the North as analogous to the immigrant generation of a white ethnic group in the United States (Lieberman, 1973). In this case, we can ask if differences exist between the two birthplace groups in their propensity to make *Who's Who* that are analogous to those found between European generations. Listed in Table 6 in the first column is the percent southern-born among all American-born blacks in the directory in each period. There is a surprising increase in the first 20 years from 81 to 87% southern, which is then followed by a sharp drop-off in the ensuing 30 years. Obviously these figures have meaning only when compared with the southern-born percentage of all American blacks. The figures in the second column are the percentage of blacks in each period that one would expect to be of southern birth given the age distribution of persons in *Who's Who* and the proportion of southern birth in each age.⁹ A figure could not be calculated for the earliest period because the necessary cross tabulations are not available, but one can be certain it would be in excess of the 92% reported for 1944.

Southern blacks in each period were less likely to make it in *Who's Who* than were northern-born blacks. In no small way this reflects the opportunity structure being even more limited in the South than in the North. Indeed, there is evidence that Southerners in *Who's Who* generally had higher outmigration rates (Gee, 1937). The rise between 1924 and 1944 in the southern role is somewhat puzzling in view of the decline in their proportion of the black population. One may speculate that it is probably due to the extraordinary

Table 6. Percent of American Blacks in *Who's Who* Born in the South

Year	Actual	Expected
1924-25	81	N.A.
1944-45	87	92
1974-75	59	80

handicaps experienced by the adult cohorts alive in 1924. Considering that many of the people who make it into *Who's Who* are relatively old, it means that a sizable number of those listed in the early edition had been born during slavery or shortly after its demise. Hence the southern-born probably had a relatively slight chance of reaching some form of national eminence when compared with northern blacks. Thus, although the southern component of the black population declined between 1924 and 1944, its decline was probably not yet that great, particularly in the crucial older ages, and this drop was therefore more than compensated for by the relative increases in the opportunities for southern-born blacks making it in *Who's Who*. Bear in mind, however, that the northern-born blacks were still relatively more apt to reach such eminence.

The shift between 1944 and 1974 is rather striking; the gap between actual and expected southern-born representation actually widened during this span. Since the occupational distribution of blacks listed in *Who's Who* has changed radically between 1944 and 1974, birthplace differences among blacks in these occupations could possibly help to account for the remarkable drop in southern-born blacks listed in *Who's Who*. Indeed, singers and musicians were much less likely to be of southern birth than were black academics; but changes in occupational composition go only a small way in explaining the sharp drop-off in the southern-born component in *Who's Who*. We are unable to determine whether the greater opportunities experienced by blacks in recent decades first occurred in the North or some other factor(s) operated, but this is a matter which calls for further work. Incidentally, so too does the curious finding about birthplace and occupational activity; in 1974-75, 79% of

⁹ These are based on the age distribution of blacks in *Who's Who* coupled with the percentage of all blacks in the United States at each age who were born in the South.

professors in *Who's Who* were of southern birth, and likewise 71% of the athletes, but only 29% of blacks in music were born in the South. In terms of the basic issue, however, the data clearly indicate that generally southern-born blacks are less likely to achieve recognition in *Who's Who*—a pattern analogous to that experienced by the white groups.

DIFFERENT CAREER PATHS: A CLOSER LOOK AT LAWYERS

One of the most subtle but important questions deals with how ethnic groups with the same training differ in the paths they may take to national eminence. Persons with a law degree are particularly interesting because a wide variety of career routes to *Who's Who* is possible. Among these are: various government activities, including both elected and appointed positions; a partnership in a prestigious law firm that serves blue-chip corporations and other prominent clients; employment in the major corporations themselves as the in-house legal chief or in a major nonlegal administrative post; positions on the board of such corporations. Accordingly there is the possibility of determining whether the law, like the entertainment situation described earlier, has different routes for blacks and the white ethnic groups.

For this purpose, all persons who had a law degree in the survey were included regardless of whether their current occupation listed in Table 4 is lawyer. The numbers are still rather small and the conclusions are tenuous. Many lawyers, particularly those apt to be selected for *Who's Who*, move in and out of different activities or hold several affiliations simultaneously. Accordingly, we have made no attempt to classify them exclusively in terms of one activity or another, but have listed them in more than one class if that was appropriate.

Earlier in this century the law provided very little opportunity for blacks to get anywhere. They were more or less wiped out in the South (Myrdal, 1944:325-6), there was only a small population base in the North to support political ambitions, and discrimination was too great for cor-

porate activities to provide much of an opportunity for either employment in the law firms that served them or with the corporations themselves. In 1924 there were only five eminent blacks with a law degree, 6% of all blacks listed. Of these, two had connections at one time or another with government. The percentage affiliated with the government has increased considerably through the years to the point that 11 of the 13 eminent blacks holding a law degree in 1974 had government linkages—the highest percentage of any of the groups (85%). At present, it is largely through government affiliations that blacks with a law degree can make these listings. Only one black in any of the three samples had a law degree *and* corporate affiliation. This was the founder, editor, and publisher of the black newspaper, *Chicago Defender*, who was president and treasurer of the publishing company.

If it is clear that blacks have had a difficult time getting anywhere with a law degree in the corporate world, it is also clear that English surname whites were in the opposite situation in both the midforties and midseventies. Of 13 English surname lawyers in 1944-45, six were affiliated with government and seven with corporations. In 1974-75, six were government and eight were corporate. In 1944-45, by contrast the relative numbers for government vs. corporate affiliations were, respectively, 7 and 2 for Italians, 17 and 1 for Jews, 6 and 1 for Scandinavians, and 8 and 2 for Slavic names with a law degree. For the English, ethnic origin is not a disadvantage in politics, particularly on the highest levels of government, but there are opportunities open to them in the corporate world that until recent years were essentially not available to blacks or some of the other white groups.

Regarding the latter groups, one observes a position intermediate between blacks and the English. Among Jews there has been a decline in the proportion affiliated with government, particularly in the post-World War II period, such that their concentration in this area in the latter period is not much greater than that reported among the English—13 lawyers with government affiliation vs. 14 with corporate

ties in the 1974 sample. The Slavs have also exhibited a sharp drop in their concentration in government since World War II but these shifts are less striking for Scandinavians and Italians. It is clear that blacks are lagging behind the white groups in the domains where their lawyers can make it, with a thrust towards government occurring at a time when its relative importance is declining for the other groups.¹⁰

A BRIEF CONCLUDING COMMENT

There is no point in attempting to review all of the specific findings reported in this comparative study of ethnic pathways to *Who's Who* and their frequency of attainment. It is clear that blacks at the very outset of the period were strikingly different from the white groups in the degree to which they could only attain prominence in a segregated black world. The new European groups differed from blacks in several ways. Their rates of eminence, although quite low when compared with English-Americans or the national average, were still initially higher than the black rate. Moreover, between 1924 and 1944 they began to increase whereas the black rate was more or less stagnant. Blacks have begun to move in the post-World War II period, but they are starting with a very low base point compared with the new Europeans and are still far behind. Several of the new European groups are still behind the national average themselves, but the relative standing of the older stock English-Americans is no longer as dominant as it once was.

A major difference between the new Europeans and blacks stems from the cultural position of the groups. What was distinctively black in the arts was not particularly appreciated by the larger white-dominated society in the sense of attaching much esteem or prestige to black culture. By contrast, the European immigrant groups, although highly despised, did have some members who were able to

use their "high culture" as a pathway to distinction since it was considered part of western tradition. This also meant that whites from these groups could break into a national network whereas blacks could not. One is reminded of the fact that most all of the white ethnic groups were able to generate ethnic cooking that was attractive to others whereas this was not the case for blacks.

One similarity that does seem to exist between the groups is that blacks appear to be following some of the same pathways to eminence as these new immigrant groups pursued in earlier periods; for example, government and music. One of the unrecognized features of sports and entertainment is not merely that successful blacks in these pursuits serve as role models, but rather that these pursuits themselves are, in historical terms, relatively unique in providing a means for blacks to attain prominence on a national stage in competition with whites for a market that is neither restricted nor segregated. This is strikingly different from the major routes to eminence available to blacks only a few decades ago, but it is similar to the pathways pursued by the new European groups from the outset. However, it would be a mistake to assume that the patterns will be fully analogous. This is because blacks are beginning to make their move at a time when the society itself has changed.

APPENDIX

DETERMINATION OF RATES

The Social Security Administration not only tabulates the total number of persons who have ever received a social security number since the inception of the program in 1936, but they also provide analogous tabulations for specific surnames. Through September 1974 there were 239,927,977 records issued (Social Security Administration, 1975), which means that the U.S. population around midyear of 1974 was about .88 of this number. Even though a large number were issued to persons who by now are deceased, it is possible to estimate the underlying population for each set of ethnic surnames if one assumes that this ratio applies about equally to all of the ethnic surnames used in this study. For example, there were 199,446 persons with certain Italian surnames on the Social Security roles in 1974. Multiplying this figure by .88, we estimate the number of persons with such surnames in the United States

¹⁰ The third important category of eminent lawyer activity, law schools, is not considered because we have discussed academics earlier. All other sources of eminence are too small in number to be analyzed here.

population to be 175,512 and this figure was then used to determine the denominator for the incidence of Italians in *Who's Who*. (The numerator, however, is not the entire 125 Italians selected for 1974, but considerably less than that because there were not enough Italians in *Who's Who* with these surnames to give a big enough N. Accordingly, we added other Italian surnames from Smith, 1973.) This procedure was followed for each of the white groups in 1974. It assumes, of course, that the .88 ratio is the same for all of the groups. In effect, this assumes that the relative number of persons in the United States with a given set of surnames is the same as their proportion of all persons on the Social Security roles.

For earlier periods, we assumed that the specified ethnic surnames for a given group was approximately the same proportion of the total U.S. population in 1924 and 1944 as it was in 1974 and hence, using the U.S. population figures for the appropriate year, estimated the group's underlying denominator for their *Who's Who* listings. This basic procedure was modified to take into account the possibility that a given set of ethnic surnames may have expanded or declined over time in its relative numerical importance in the nation. This was done through a simple regression procedure because surname lists were not available for 1944 and, of course, the Social Security Act had not been passed in 1924. But we did have Social Security surname lists for 1936 (Weyl, 1966) and 1964 (unpublished data furnished by the Social Security Administration). An example will make these steps clear. In the preceding paragraph we inferred that there were 175,512 persons with certain Italian surnames in the United States in 1974. Dividing this figure by the entire United States population, we infer that these specific Italian surnames are .000830 of the total population in 1974. Using the 1964 and 1936 surname lists from the Social Security Administration and adjusting by a ratio between the total United States population in each period and the total number of SAA names (which leads to ratios of 1.15 and 1.43, respectively), we infer that these specific Italian surnames were .000875 and .000851 of the nation's population. Regressing these proportions on the years for which they were obtained, it is possible to estimate the surnames' proportion of the population in 1924 and 1944 (using the regression equation with x as 1924 and 1944). In the event that there is no correlation between the proportion and time, this procedure will generate the mean proportion for the three periods, which is not an unreasonable solution either.

Two special problems exist for persons of English origin. Weyl (1966:22) found some indication of differences between English surnames in their *Who's Who* rates and our results confirm this, although too late to affect our procedure for using English surname data to get occupational and other char-

acteristics of those listed in *Who's Who* (this is largely based on persons with Walker as a surname, with blacks excluded through a check with the black lists and the black directory). However, for computing the English rates of eminence, we used six surnames: Carter, Clark, Hall, Hill, Walker, and Wright. A second adjustment was required because there is a certain overlap between English surnames and the surnames found among blacks. According to Weyl (1966:21), about 19% of persons with these English names in the United States are black. The English rate was therefore adjusted by dividing by .81 ($1 - .19$).

It is not necessary to use the surname procedure for the black population. For both 1924 and 1944 we have lists purporting to include all blacks reported in *Who's Who*. Accordingly, we simply divide these numbers by the total black population in each year to obtain an appropriate rate. For 1974 there was no such listing and an alternate procedure was used. The sample of blacks listed in the 1974-75 *Who's Who* was obtained within an alphabetical range beginning with "A" until the desired number was obtained. The ratio of the total black listings known for 1944-45 to the number that would have been obtained using an analogous procedure for 1944 was determined and then multiplied by the number obtained in 1974-75. This provided an estimate of the total black listings in *Who's Who* in 1974 and could then be divided by the total black population in the nation for that year.

Finally, in order to obtain a prevalence rate for 1974 comparable to the rates reported in Larson (1958) for earlier periods, the number of listings in a sample of pages in *Who's Who* was multiplied by the total number of pages in the directory and then divided by the population figure for the nation.

There are a number of obviously arbitrary decisions involved in these rates, for example, all sorts of assumptions are made on the basis of small samples. The figures reported are basically prevalence rates rather than incidence rates, that is, the estimated number of persons of a given group is expressed per 10,000 members of the population alive presently rather than in terms of the probability of entering *Who's Who* during a specified period of time. Since there are some survivors from one *Who's Who* to another, albeit not too many, ethnic differences in survivorship could affect inferences about change. Likewise, no adjustment is made for the fact that age is related to the chances of being included and, in turn, the ethnic groups differ among themselves in their age composition. These and other less than ideal procedures aside, there is every reason to believe that the results reported in Table 1 represent the best estimate possible at this time of the ethnic prevalence rates in *Who's Who* and provide reasonable comparisons of their changes over time.

MANUSCRIPTS FOR THE ASA ROSE SOCIOLOGY SERIES

Manuscripts (100 to 300 typed pages) are solicited for publication in the *ASA Arnold and Caroline Rose Monograph Series*. The Series welcomes a variety of types of sociological work—qualitative or quantitative empirical studies, and theoretical or methodological treatises. An author should submit three copies of a manuscript for consideration to the Series Editor, Professor Robin M. Williams, Jr., Department of Sociology, Cornell University, Ithaca, New York 14853.

EQUAL EMPLOYMENT OPPORTUNITY LEGISLATION AND THE INCOME OF WOMEN AND NONWHITES*

PAUL BURSTEIN
Yale University

American Sociological Review 1979, Vol. 44 (June):367-391

This article examines the impact of federal equal employment opportunity legislation on the income of white women, nonwhite women, and nonwhite men relative to the income of white men at the national level since the late 1940s. The analysis differs from those previously published in comparing all groups with white men, including changes in attitudes in the analysis, and dealing in detail with enforcement of the laws. The model developed in the article works well when used to examine increases in nonwhite income, but does not deal satisfactorily with the incomes of white women. The findings indicate that there are important differences between race and sex discrimination which will have to be taken into account in theories of labor market discrimination.

The struggle to end discrimination against minorities and women has played a central part in recent American history. Much of the struggle has been devoted to the achievement of equal opportunity in employment. To help women and minorities achieve equal opportunity, Congress passed several equal employment opportunity (EEO) laws in the 1960s and 1970s. The aim of this article is to gauge the national-level impact of these laws on the incomes of women and nonwhites relative to those of white men. The focus will be on the four laws most directly related to employment in the entire civilian labor force—the Equal Pay Act of 1963, Title VII of the Civil Rights Act of 1964, and the 1972 laws amending each of them.¹

The analysis differs in three significant respects from comparable ones published previously. First, the incomes of white and nonwhite women, as well as nonwhite men, will be compared with those of white men, who were clearly intended to be the comparison group in the EEO laws. No previous aggregate-level studies gauge the laws' impact on women relative to white men.

Second, changes in attitudes toward discrimination will be included in the models. The economic theory of employment discrimination, which provides the theoretical framework for this study, hypothesizes that the white male "taste for discrimination" will affect the incomes of those discriminated against. Past applications of the theory, however, make no attempt to examine the consequences of

* Address all communications to: Paul Burstein; Department of Sociology; Yale University; New Haven, CT 06520.

I would like to thank Richard Berk, Claude Fischer, Owen Fiss, Florence Katz, and Stanley Masters for helpful comments on an earlier draft of this paper. An earlier version was presented at the 1979 annual meeting of the Eastern Sociological Society, New York.

¹ The Equal Pay Act (Public Law 88-38, 77 U.S. Statutes At-Large 56-57) prohibited differential rates of pay for women and men who do equal work, with some exceptions. Title VII (PL 88-352, 78 Stat. 241-268) prohibited many discriminatory employment practices. Enforcement relied very heavily on the private actions of aggrieved individuals; the Equal Employment Opportunity Commission (EEOC) created by the Act had no enforcement powers of its own; its role was limited primarily to conciliation.

Among the significant exceptions to the prohibitions against discrimination was one that permits discrimination on the basis of sex (but not race) when it is found to be a "bona fide occupational qualification" for the job. The Equal Employment Opportunity Act of 1972 (PL 92-261, 86 Stat. 103-113) extended the coverage of Title VII and gave the EEOC the power to go to court when conciliation efforts failed. Section 906 of the Education Amendments of 1972 (PL 92-318, 86 Stat. 235-381) abolished many of the exemptions in the Equal Pay Act. For detailed descriptions and analyses of these and related laws, see Task Force on Women, 1975: chap. 3; Gitt and Gelb, 1977; Harvard Law Review, 1971; Fiss, 1971. Other federal laws may affect the economic situation of women and minorities; this paper deals with those laws intended to have the most direct and widespread impact.

changes in tastes. This paper will demonstrate the importance of including approximate measures of tastes in the analysis.

Third, the paper will refine considerably the treatment of EEO law enforcement, which was measured in very simple ways in past work.

The improved model developed in the paper works well when used to examine changes in the incomes of nonwhite men and women relative to those of white men, but does not deal satisfactorily with changes in the incomes of white women. The findings indicate that there are important differences between race and sex discrimination which will have to be taken into account in theories of labor market discrimination.

EMPIRICAL CONTROVERSY

Have EEO laws had a significant, favorable impact on the economic situation of women and minority group members? Experts disagree. Legal scholars involved in employment discrimination cases tend to see the laws' effects as slow and uncertain. Professor Derrick Bell, Jr. (1977:681) of Harvard Law School, for example, introduces a symposium on equal employment law by writing that he has

serious doubt as to the long-term effectiveness and worth of equal employment laws. . . . If the country were really committed to eradicating the social and economic burdens borne by the victims of employment discrimination, it would have fashioned a far more efficacious means of accomplishing this result. At present, the law channels charges of employment discrimination into a burdensome, conciliation-oriented administrative structure that functions, in the mean, on a case-by-case basis, depending on effectively-prosecuted litigation and a sympathetic judiciary for even the hard-won progress thus far achieved. Even the most wildly optimistic among us cannot reasonably hope that reliance on this complex and uncertain process will close the wide gap in income standards and unemployment rates between black and white and male and female employees.

Herbert Hill, the foremost expert on black labor and the American legal system, arrives at a cautious but somewhat less pessimistic conclusion about blacks in

the labor force. He feels that the apparent victory achieved by the passage of the 1964 Civil Rights Act was largely illusory in the short-run because employers and unions vigorously defended their traditional discriminatory practices for years. Years of litigation began to turn the tide, however, and he concludes that "[b]y the mid-1970s the impact of the law was evident as court orders began to make the elimination of racial discrimination an economic necessity" (1977:4).

Neither Bell nor Hill presents quantitative evidence to support his conclusions. The most sanguine conclusions about the impact of EEO legislation are those of Richard Freeman and Stanley Masters, economists who attempted to analyze the laws' impact on black-white economic differences. Freeman (1973:118-9) concludes:

The income and occupational position of black workers improved significantly relative to those of whites in the sixties. . . . Much of the improvement in the black economic position that took place in the late sixties appears to be the result of governmental and related antidiscriminatory activity associated with the 1964 Civil Rights Act.

Masters (1975:143) similarly concludes that his findings support "the liberal view that there should be a continuous improvement in the relative position of blacks once some precipitous event like the Civil Rights Act and the pressures that led to it have occurred."²

² Other works on the aggregate-level consequences of federal legislation attempt to show that the gains of black men have been limited to the South (Vroman, 1974; McCrone and Hardy, 1978). There are also some studies which proceed at lower levels of aggregation, such as industries or SMSAs; findings about the efficacy of EEOC enforcement, Office of Federal Contract Compliance activities, and other programs, are mixed; see, e.g., Adams, 1972; Beller, 1977; Bergmann and Lyle, 1971; Heckman and Wolpin, 1976; Smith and Welch, 1977. A study of Canadian equal pay legislation claimed to show it had no effect (Gunderson, 1975).

There are also a number of studies which purport to gauge the impact of civil rights laws by simply presenting data on black-white or female-male differences along some dimension before and after the passage of the laws, without controlling for any other factors; Niemi (1974) is typical. The conclusions of these latter studies, carried out without controls for other relevant variables, cannot be taken seriously.

Thus, those who deal with the laws tend to see their effects as slow and uncertain. Those who deal with income data tend to see the laws' effect as immediate and consequential so far as the black-white income ratio for males is concerned, and have nothing to say about the incomes of women as compared with white men.

THEORETICAL ISSUES AND MODELS OF LEGISLATIVE IMPACT

Economic Models: Theory vs. Application

Almost all the quantitative work on the effects of EEO legislation has been written by economists who draw heavily on Becker's (1971) *Economics of Discrimination*. Three studies form the core of empirical work on the aggregate-level effects of EEO legislation: Landes's (1968) article on the impact of state fair employment practices laws on the economic status of nonwhites; Freeman's (1973) paper on the impact of the 1964 Civil Rights Act; and Masters's (1975: chap. 6) chapter on the effects of the 1964 Act on the economic situation of black men. Other works use very similar theoretical approaches, variables, and analytic techniques.

Although the economic theory of labor market discrimination has ramified beyond concise description (see Marshall, 1974; Blau and Jusenius, 1976), those aspects of the theory applied in the empirical works can be summarized as follows: Differences in the labor market treatment of racial minorities or women begin with the taste for discrimination of employers, employees, or customers. Because white men do not like members of other social categories in some way—they may not like to work with them, to see them have equal status positions, or whatever—they act as if they are willing to pay a monetary price to avoid associating with members of such categories. White employers who have a taste for discrimination, for example, may be willing to hire black workers only if the blacks will work for lower wages than whites of equal skill, with the extra money going to the employers as payment for overcoming their aversion to blacks. Under specified conditions, this behavior lowers the relative incomes of blacks. Laws prohibiting discrimination in

the labor market may work if they raise the price discriminators have to pay for indulging their tastes—by threatening them with fines or with having to make compensatory payments to those discriminated against, for example.³

Thus, Freeman (1973:93–4) argues theoretically that two important forces appear to have reduced discrimination in the labor market between 1948 and 1972: a change in the demand or taste for discrimination, which plays the critical role in Becker's theoretical model, and a change in the cost of discrimination due to enforcement of Title VII of the 1964 Civil Rights Act and other national policies. Masters (1975:141) similarly argues that changes in the labor market position of blacks could have been brought about by legislation and attitude change.

Within this theoretical context, those studying the consequences of EEO legislation pursue a similar course: they basically regress some measure of black-white differences in the economic sphere, such as the black-white income ratio, on variables gauging the general state of the economy and the passage or enforcement of EEO laws. Finding significant coefficients for the EEO variables, they conclude that the legislation has significantly reduced some economic differences between blacks and whites (though Landes finds this may have been at the cost of increased black unemployment).

Unfortunately, the studies are flawed in ways that make it difficult to accept their findings. Both Freeman and Masters argue that changes in black income may be due to two factors: change in the demand for discrimination and EEO legislation. The empirical analyses include only one of the factors, however—EEO enforcement—and attribute changes in black incomes to this factor alone. Although both are tentative in their conclusions (with Masters admitting that his es-

³ Although the notion that discrimination can be reduced by making it expensive is formally derived from economic theory, economic sanctions are seen as the most effective way to reduce discrimination by many others as well; see Hill, 1977:4; Levitan et al., 1975: chap. 13; for evidence of corporate attitudes, see "Business Resisting U.S. on Halting Work Bias," *New York Times*, May 26, 1978: D1.

timates are upperbound estimates of the true impact of the laws), neither tries to include changes in the taste or demand for discrimination explicitly in the analyses (see Freeman, 1973:94, 105; Masters, 1975:141, 143).

Past analyses thus appear to have a serious specification problem. EEO enforcement activities are positively correlated with increases in favorable attitudes towards blacks and women in the labor force. Consequently, including a measure of demand for discrimination in the analysis would reduce the apparent impact of EEO legislation, possibly to insignificance.⁴

Economists have developed an elaborate rationale for not using attitude data to measure tastes or demand, and the argument makes sense in many cases.⁵ To a sociologist, however, it seems plausible that the factors that probably helped produce EEO legislation in the first place—changing attitudes, in particular—continue to operate after the law is passed and have an independent impact on the economic standing of groups protected by the legislation. It seems much better to include a rough proxy for taste for discrimination in the analysis than to ignore it completely.

⁴ The only empirical attempt to measure taste for discrimination in a study of EEO legislation impact is Bergmann and Lyle's (1971) study of black-white occupational differences across metropolitan areas and industries. Using the 1968 Wallace vote as a proxy for white taste for discrimination, they found that this variable explained black-white differences better than differences in education did, and *better than the existence of a state fair employment practices law*. But they did not use actual attitude data or follow up on the idea.

⁵ Strictly speaking, there is a difference between a taste for discrimination and a demand for it. Changes in tastes, which economists tend to consider entirely exogenous to their models, may lead to changes in demand; this may be seen very roughly as akin to the gap between attitudes and behavior in social psychological research. In practice, neither tastes nor demand for discrimination are measured directly. Berger's sophisticated discussion of the factors affecting employment discrimination states many of the same issues in sociological language, and is consistent with the argument made here; unfortunately, his empirical work cannot answer the questions raised by his theoretical formulation; see Berger, 1967: chap. 4; Freeman, 1973:93-4; Becker, 1971: chap. 9.

Unfortunately, the hypothesis that attitudes about discrimination and EEO laws may affect the economic status of women or nonwhites has not been tested by sociologists. Changes in the economic status of blacks relative to whites and women relative to men are a major concern in the recent literature on stratification, but most works either attribute such changes partly to changes in laws and attitudes without providing evidence (Farley, 1977:206), mention the possibility that laws may have had an impact without investigating it (e.g., Featherman and Hauser, 1976:464; Snyder and Hudis, 1976:215, 231), or simply ignore the legislation when discussing the economic status of women and blacks.

Realism in the Analysis of Enforcement

There is an additional difficulty in the extant work. Although Landes and Freeman try alternative specifications of their EEO enforcement variables, their measures do not seem like realistic operationalizations of their theory.⁶ They are interested, essentially, in costs imposed on employers (or unions or employees) for discriminating; their notion is that employers will change their behavior once they realize that it will be costly not to do so. Ideally, therefore, the best predictor of EEO legislation efficacy should be a measure of the costs incurred by employers who continue to discriminate after discrimination is prohibited—a measure of the probability of being caught multiplied by the penalty imposed would be best. Such a measure is impossible to find (though some possible alternatives will be discussed below), but the measures actually employed, EEOC expenditures measured different ways, seem insufficient. During the entire period studied by Freeman, the EEOC had no enforcement powers; it was limited to attempting to conciliate complaints of discrimination. Freeman acknowledges that the EEOC variable is a proxy for all federal enforce-

⁶ Landes is less relevant here because he was concerned with state legislation. Masters's operationalization is the simplest of all—he simply includes two time trend variables and a dummy variable to mark the passage of Title VII.

ment activities, but this does not seem adequate justification for the magnitude of the gap between the variables required by the theory—actual costs—and those used.

In order to assess satisfactorily the impact of EEO legislation, realism about the enforcement process seems essential; the measures of enforcement effort should have some fairly clear relationship to the actual likelihood that those who discriminate will have to pay a penalty for doing so.

This consideration leads to three changes in the way enforcement will be dealt with here, as compared with past work. First, although there is no way to measure the actual cost to employers of disobeying or complying with the laws, data are available on the amount of money awarded under the provision of the Equal Pay Act to those discriminated against. These data will be included in the analysis.

Second, because the binding enforcement procedures of Title VII involve court proceedings (rather than administratively issued cease-and-desist orders or some other mechanism), some measure of the decisions being made by the higher U.S. courts on EEO cases should be included in the analysis. When the laws were passed, it was not known, of course, how they would be interpreted by the courts. Employers would be most likely to take the law seriously, it can be argued, only if it were clear that the law would be interpreted to make employers liable to substantial financial penalties if they continued to discriminate (see, e.g., Levitan et al., 1975:290–2). The first U.S. Court of Appeals decision that could be seen as making this point clearly was not decided, however, until 1971 (*Robinson v. Lorillard Corp.*, 44 F.2d 791; petition for writ of certiorari dismissed, 404 U.S. 1006 [1971]; also see *Albermarle Paper Co. v. Moody*, 422 U.S. 405 [1975]). The Supreme Court did not decide any Title VII cases until 1971 (see Equal Employment Opportunity Commission, 1972:23–31), and doctrine remains unsettled in many areas (see Venick and Lane, 1977; compare *University of California Regents v. Bakke*, 46 U.S. Law Week 4896–4936 with *Communication Workers of America v.*

EEOC, 46 U.S. Law Week 3801; see also *Newsweek*, July 10, 1978:32, “The Hard Cases Coming”).

Past empirical work has thus ignored the cumbersomeness of the legal process and the slowness with which the meaning of the laws becomes clear (see Bell’s [1977] statement quoted above, and, e.g., Levine and Montcalmo, 1971). This paper will attempt to take actual enforcement possibilities into account by examining all EEO decisions by the U.S. Supreme Court and Court of Appeals to determine the number and proportion of cases decided in favor of women and racial minorities.⁷

Third, EEO legislation can be effective only if it is utilized; a law that is too cumbersome and costly for people to use is not likely to be effective. Measures of EEOC expenditures, Equal Pay Act payments, and court decisions essentially gauge the supply of enforcement activities. It seems important to gauge the effective demand for EEO enforcement as well; this can be done by considering the number of charges brought to the EEOC and the number of cases brought before the courts.

As applied to the study of EEO legislation, Becker’s theory has been taken to imply that a decline in the taste for discrimination and an increase in its cost will lead to an increase in the relative income of the group that has been discriminated against, everything else being equal. That is also the point of view of this paper. But this article differs from past work in proposing that changes in taste should be included explicitly in the analysis and that it is necessary to be as realistic as possible in the analysis of costs likely to be imposed upon discriminators.

RELATIVE INCOMES OF WOMEN AND NONWHITES: DESIGN AND DATA

What Is to Be Explained

The analysis focuses on changes in the incomes of nonwhite men, nonwhite

⁷ In addition, EEOC expenditures could be hypothesized to be more effective after the EEOC was given enforcement powers in 1972 than they were before. Unfortunately, the time since 1972 is too brief to permit tests of differential impact.

women, and white women, each measured as a percentage of the income of white men. Three time series are analyzed: median wage and salary income of year-round full-time workers, 1955–1975; median wage and salary income of all those with such income, 1948–1975; and median total money income, 1948–1975 (these are the entire periods for which data are available on an annual basis; for information on the sources and construction of all variables, see the Appendix). Each time series can be usefully distinguished from the others. The measure of the earnings of full-time workers is probably the best measure of what EEO legislation is designed to affect—opportunities available to full-time employed members of the labor force. Median earnings of all labor force participants captures changes in opportunities available to those employed part-time, voluntarily or otherwise. And median total money income, by including income from social security payments, welfare, dividends, interest, etc., is probably the best measure of overall economic well-being (see Freeman, 1973:73; Masters, 1975:142).⁸

As described above, past analyses have compared the incomes of nonwhite or black men with those of white men. Freeman also analyzes the determinants of black female income, measured as a proportion of white female income; no analyses have compared female income with white male income in the context of EEO impact.⁹

⁸ Determinants of mean total money income were also analyzed, but the result did not differ in any material way from those concerning median total income, and have been excluded to shorten the presentation. Means and medians are the best simple measures of group income, but they do not adequately represent all aspects of income distributions, such as increasing variance in income within social groups; see Wilson, 1978; Villemez and Rowe, 1975. These problems will be dealt with elsewhere.

⁹ Stevenson (1975) analyzes changes in white female income relative to that of white males, but does not consider the impact of EEO legislation. This analysis contrasts whites to nonwhites, not blacks. This is partly because the EEO laws prohibit all racial discrimination, not just discrimination against blacks, and partly because the data for much of the time series are available only for nonwhites and whites. Because blacks are about 90% of nonwhites, the results would be altered very little in any case.

This analysis breaks precedent by comparing the incomes of nonwhite and white women with those of white men. The justification for doing this is straightforward. The manifest purpose of the legislation was to help ensure that those who had been discriminated against would in the future be treated as well as white men. Because white men are the implicit comparison group in the law, they should be the comparison group in any study of relative incomes.¹⁰ In addition, comparing nonwhite women with white women, as has been customary, rather than with white men, exaggerates their progress, because they are being compared with a group that suffers itself from discrimination (Bell, 1972:365; Figures 1 and 2 will make this very clear).

Explaining Income Differences

Changes in the relative incomes of blacks and whites and men and women customarily are seen as determined mainly by four types of variables: those measuring the relative productivity of members of the different groups, the overall demand for labor in the economy, changes in attitudes toward different groups, and EEO enforcement activity (see, for example, Arrow, 1972; Bell, 1974; Haworth et al., 1975; and, of course, Freeman, 1973, and Masters, 1975).¹¹ All four will be included in this analysis.

Even if all labor market discrimination were to disappear immediately, blacks and women would not achieve economic equality with white men for a long time,

¹⁰ One justification in past work for comparing women of different races with each other rather than with men was probably that this implicitly controlled for many differences between men and women in labor force behavior. Although some remain convinced that many of these differences are voluntary (Gwartney and Stroup, 1973), the women's movement and the inclusion of sex discrimination in the EEO legislation makes this "voluntariness" problematic. Because the legislation is intended to reduce many of the presumed differences in labor force behavior, it is inappropriate to build such presumptions into the analysis.

¹¹ Masters and others have tried to show that a variety of other possible influences, such as migration and housing segregation, do not have a significant impact on black-white differences (Masters, 1975: chaps. 3–5).

because they (particularly blacks) have been denied equal access to education and training. Members of groups that have been discriminated against can expect to achieve equality in incomes only as they approach equality in productivity. In this analysis, the measure of relative productivity will be the ratio of median years of education completed by members of the relevant groups. This is a crude gauge of relative productivity, but is standard and practical (see Welch, 1973).

The economic progress of groups that have been discriminated against is widely seen as dependent upon tight labor markets. Because white men can resist opening new job opportunities to nonwhites and women—through union seniority rules, on-the-job hostility and sabotage, etc.—nonwhite and female progress is much more likely when there are lots of jobs available (see, e.g., Bell, 1974). The demand for labor will be measured by the overall national unemployment rate.

Attitudes toward nonwhites and women in the labor force, taken as rough indices of tastes for discrimination, will be measured in terms of the only three questions asked repeatedly in national surveys during most of the period since 1948. The first was asked of whites six times between 1944 and 1972: "Do you think Negroes should have as good a chance as white people to get any kind of job, or do you think white people should have the first chance at any kind of job?" The second was asked of adult Americans five times between 1942 and 1962: "Do you approve of paying women the same salaries as men, if they are doing the same work?" The third was asked five times between 1938 and 1976: "Do you approve of a married woman earning money in business or industry if she has a husband capable of supporting her?" Public opinion toward blacks and women in the labor force became steadily more favorable over time, making it possible to estimate attitudes for those years when the questions were not asked (R^2 's for regressions of attitudes on time were .99, .58, and .94 respectively; see Figure 3 and Appendix for details).¹²

¹² These data are clearly not the best indicators of taste for discrimination that could be devised.

EEO enforcement activity was measured in a variety of ways. The supply of administrative EEO enforcement was measured in terms of expenditures by the EEOC, expenditures per black and female member of the labor force, cumulated expenditures, expenditures per charge processed, and Equal Pay Act underpayments disclosed. Judicial enforcement was gauged by the annual and cumulative number and proportion of race and sex discrimination cases decided in favor of women or minorities by U.S. Courts of Appeals and the U.S. Supreme Court. The demand for EEO enforcement was measured in terms of the number of actionable complaints of discrimination—race, sex, and total—processed by the EEOC each year. The aim was to gauge in many ways the intensity of the problem, the resources available to cope with discrimination—both total incidence and complaints—and the timing of effective implementation of the law.

Some Expectations

The basic hypothesis of the study is straightforward: everything else being equal, increases in the productivity of women and nonwhites, decreases in unemployment, decreases in discriminatory attitudes, and increases in the supply of and demand for EEO enforcement activities should have independent positive effects on the incomes of nonwhite men, nonwhite women, and white women relative to those of white men.

One caveat is in order. Although neither Becker nor those who have tested his theory generally distinguish between race discrimination and sex discrimination (see Becker, 1971: 106–7), other people have argued that the two are different with different causes and consequences that bear on the analysis. As it turns out, the

Ideally, we would like annual data on attitudes of theoretically distinguishable groups—employees, employers, customers—toward various aspects of labor market relationships (willingness to work with members of particular groups, to have them as supervisors, etc.). But the data used are the only relevant time series data available. For a more general review of changes in attitudes toward blacks, see Burstein, forthcoming.

hypothesis is generally supported by the evidence for nonwhite men and women, but not for white women. Some possible reasons for this will be discussed below.

FINDINGS

A Preliminary Picture of the Data

Figures 1 through 5 and Table 1 provide some essential preliminary information about the phenomena under consideration.

Figures 1 and 2 portray changes in the ratio of the incomes of nonwhite men, nonwhite women, and white women to those of white men. The figures show that nonwhite men and women have made considerable gains in relative income during the last 20 to 30 years, but that they still have a long way to go before catching up with white men. The figures show a slight upward trend for the entire period; the trend appears to have accelerated since Title VII went into effect in 1965, and may even have accelerated slightly again since 1972, when the law's enforcement provisions were strengthened. Thus, for example, the ratio of nonwhite to white male wage and salary incomes among year-round full-time employees rose only from .63 in 1955 to .66 in 1964, but then rose to .70 in 1972 and .77 in 1975.

The picture is quite different, however, for white women. The ratio of white female to male wage and salary incomes for full-time workers fell fairly steadily from approximately .64 in 1955 to .58 in 1974, and the ratio of median total money income has also fallen (the picture of earnings for all in the labor force is like the picture for full-time workers, and is left out to save space). The ratio for total money income stopped its decline and then began to rise after the passage of Title VII and the Equal Pay Act, but the ratio for full-time workers did not. White women have not been gaining from recent social and legal changes in the same way as nonwhite men and women. (The figures also demonstrate that analyses which compare nonwhite women with white women rather than white men will exaggerate the progress of nonwhite women in the struggle against discrimination.)

Figure 3 presents estimated changes in public opinion on the labor force participation of women and nonwhites since the 1940s. At least with regard to statements of principle, prejudice against women in the labor force seems to be a greater problem than prejudice against blacks. Almost all whites agree that blacks should have an equal chance at jobs, and have for years; change since the end of World War II has been dramatic. Changes in attitudes toward female participation in the labor force have also been great, but considerable antipathy remains; as recently as 1976, almost a third of the public still felt that women who had husbands who could support them should not work for pay (women were only slightly more favorable in their responses than men were). Nevertheless, attitudes toward both blacks and women have become much more favorable. This trend is consistent with the trend in nonwhite incomes (male and female), but is contrary to the trend in white female incomes.

Figure 4 documents the very significant increases in levels of education attained by nonwhites relative to whites. It also shows that white and nonwhite men have been catching up to the women of their own races educationally. The relative decline of educational attainment among white women is consistent with the decline in relative income documented above; whether such an interpretation makes sense substantively is a question that will be dealt with below. In any case, the educational levels of the four groups reached virtual parity by the mid-1970s.

Figure 5 gives some indication of the timing and intensity of the EEO enforcement process; it pictures the cumulative number of race and sex discrimination cases—brought under the four laws dealt with here—decided by U.S. Courts of Appeals and the Supreme Court. To the extent that a complex and controversial set of laws like the EEO laws can have substantial impact only after they have been interpreted by higher courts in a way offering some relief to the disadvantaged, the impact of the laws would be slow in coming. Although the Equal Pay Act was passed in 1963 and Title VII in 1964, with each taking effect a year later, no cases

under these statutes were decided by appellate courts until 1967, and the numbers decided grew slowly for several years thereafter. The meaning of EEO legislation and the possible magnitude of sanctions that could be applied to discriminators were not clear for years after the passage of the laws (and are still fuzzy in important areas).

Table 1 provides additional information about the EEO enforcement effort. Objectively, it is not obvious what would constitute an "adequate" enforcement effort in the short term. EEOC expenditures have risen every year, both in current and constant dollars, just about keeping pace with the increasing number of complaints ("actionable charges") made to the Commission. If we view EEOC expenditures as an investment in equal opportunity that will have effects beyond the year of the expenditures (Freeman, 1973:100), the total amount spent by the EEOC per black and female member of the labor force, cumulated over eleven years, was just under four dollars (1967 dollars). An investment of four dollars a person on a major social problem does not seem like a lot, especially when contrasted with the amount spent on training programs (Masters, 1975:152), and it is, in fact, fairly widely agreed that the EEOC is very inadequately funded considering the magnitude of its task.¹³

The table also shows that the number of charges has continued to rise, taking a particularly big jump in 1972, the year the law was strengthened. To the extent that the number of charges reflects the number of grievances, employment discrimination is hardly declining as a problem. Finally,

¹³ See Levine and Montcalmo, 1971; U.S. Commission on Civil Rights, 1977: 329-35. EEOC expenditures are just a part of total government expenditure on equalizing employment opportunities (see U.S. Office of Management and Budget, 1978:275-87), and are used here as an indicator of activity rather than as an inclusive measure (more inclusive data are not available for the entire time period). Politically, it is probably not an accident that the EEOC has been underfunded. Some members of Congress may have underestimated the magnitude of the EEOC's task and felt they were voting sufficient funds, but it is also true that, once Title VII passed, its opponents worked hard to minimize the resources available to the EEOC (see, e.g., U.S. Senate, 1970: 1043ff).

^b Estimated.

the table provides evidence that sex discrimination lagged behind race discrimination as an object of concern, both among complainants to the EEOC and in the courts, but that it is becoming an increasingly important part of the administrative and judicial caseload. In light of the figures on income presented above, this is not surprising.

In sum, the incomes and educational levels of nonwhite men and women have improved relative to those of white men, and attitudes toward blacks have become more favorable. The income and educational picture for white women is much less positive. The EEO enforcement effort was slow to begin and seems modest in intensity, but the demands placed upon the system keep increasing.

Multivariate Statistical Models and Analyses

In order to gauge the impact of likely determinants of income ratios, the nonwhite male/white male, nonwhite female/white male, and white female/white male income ratios were regressed on the measures of relative education, unemployment, attitudes, and EEO enforcement activity. There proved to be serious problems of multicollinearity among some variables, however.

Because all three measures of change in attitudes were simple time trends, they were to all intents and purposes perfectly correlated with each other, so no more than one could be used in any equation.

Changes in relative education were very highly correlated with the passage of time as well, and so were correlated very highly with changes in attitudes. The correlation of the nonwhite male/white male education ratio with attitudes on black access to jobs was .97, for example, and introducing both variables into a regression simultaneously produced the outcomes that would be expected in the presence of multicollinearity—large and substantively unlikely variances in the parameter estimates, insubstantial changes in R^2 when variables were added or removed, and decreases in computational accuracy (see the useful discussion in Rao

and Miller, 1971:46–52). This high correlation is probably not a coincidence, and a study of the relationship between the liberalization of attitudes and black access to education would be interesting itself. Within the data set and context, however, there was no way to disentangle the effects of the two variables. The same problem arose with regard to nonwhite women. With regard to white women, liberalization of attitudes has gone along with a decline in relative educational attainment. Substantively, this probably implies that changes in years of education is not a good measure of changes in productivity so far as white women are concerned (Madden, 1978), but in this case the *negative* correlation between public attitudes and educational attainment was so high that both variables could not be used in the equations simultaneously.

In the equations presented, therefore, measures of attitudes and of education are never included in the same equation (cf. Freeman, 1973:101). The extremely high correlation of the variables with each other and with the passage of time reduces the degree to which the results can answer theoretical questions about their separate effects. This is itself a significant finding, however, if only because it implies that past studies may have attributed to changes in education some consequences that were in fact the result of changes in public opinion. The multicollinearity problem does not reduce the predictive value of the equations, of course.

Similar problems arise with regard to the measures of EEO enforcement effort. Although measures such as court decisions, EEOC expenditures, and charges of discrimination can be distinguished theoretically, and although there is no theoretical reason why they should be very highly correlated, in fact nearly all the measures proved to be simple time trends very highly correlated with each other. This was true for EEOC expenditures, expenditures per covered worker, cumulated expenditures, Equal Pay Act payments, annual and total court decisions, charges handled by the EEOC, expenditures per charge, and other measures. Here, as with education and public attitudes, it proves impossible to assess

separately the effects of different interesting variables.

The following variables were included in at least some of the ordinary least-squares regressions actually run. For nonwhite men: the national unemployment rate (denoted *Unempl* in the tables); the ratio of their education to that of white men (*Educ*); the measure of attitudes toward blacks' access to jobs (*Attitude*); the percentage of court cases dealing with racial discrimination decided in favor of minorities each year, lagged one year, included because employers might get a sense for how court enforcement has been proceeding in the short term and respond accordingly (*% Cases*); cumulated EEOC expenditures per nonwhite and female member of the labor force, in constant dollars (*EEOC \$*); the cumulated number of court decisions favoring minority complainants (*N cases*); and the number of actionable charges based on race processed annually by the EEOC (*Charges*).

For nonwhite women. In theory, nonwhite women should gain from efforts to improve the economic situation of nonwhites and of women; in practice, because of the multicollinearity problems just described, it was not possible to separate the effects. The same variables were used for nonwhite women as for nonwhite men, with the exception of education, which was the ratio of nonwhite female education to white male education.

For white women. The following variables were used: the unemployment rate; the ratio of their education to that of white men; the measure of attitudes toward equal pay for equal work for woman; the percentage of court cases dealing with sex discrimination decided in favor of women each year, lagged one year; cumulated EEOC expenditures per nonwhite and female labor force member; cumulated number of court decisions favoring female complainants; and the number of actionable charges based on sex processed annually by the EEOC.

The results are presented in Tables 2 to 4. Table 2 presents the results for nonwhite men ("D-W d" is the Durbin-Watson d statistic). Overall, the results are consistent with the hypothesis that the demand for labor, educational attainment,

public attitudes, and EEO enforcement efforts all have a significant impact on the relative incomes of nonwhite men.¹⁴ It is, however, as noted above, impossible to disentangle the effects of education from those of attitudes, or of the various measures of enforcement effort from each other.¹⁵ Perhaps the most important result is that the impact of EEO legislation is not absorbed into the attitude variable—EEO laws do have an independent effect.¹⁶

Interpreting the coefficients concretely, the coefficients for education cluster around approximately .20, meaning that a 5% increase in the ratio of nonwhite male education to white male education resulted in a 1% increase in the income ratio, everything else in the equations being equal. With nonwhite male education having improved from 71% of white male education in 1948 to 96% in 1975, an increase of approximately 5% in the income ratio could be attributed to the increase in education. Similarly, an increase of about 8% of the white population feeling that blacks should have an equal chance at jobs seems to be associated with a 1% increase in the income ratio.

The unemployment rate has no significant impact on the relative income of full-time workers, as might be expected, since increases in unemployment would simply

¹⁴ The t-statistics should be interpreted cautiously. Berk and Brewer (1977) have argued that statistical inference in many econometric models rests upon untested and even untestable assumptions. Tests of statistical significance in this article mean just what they do in the other relevant studies.

¹⁵ Both Freeman and Masters include time-trend variables in their analyses. As a practical matter, the estimates of EEO impact derived here for nonwhite men will not differ all that much from Freeman's, because the attitude variables included in this study are so highly correlated with the time trend variable he included in his equations. Theoretically, however, the use of attitude data is clearly preferable—it plays a definite role in the economic theory of discrimination, while *time* is not a very useful concept theoretically. In addition, in those situations where attitudes and time are not highly correlated, the coefficients in equations not including attitudes would be biased (see Pfister, 1974:189).

¹⁶ Although the attitude change was probably partly responsible for the passage of the EEO laws, the relationship between laws and attitudes would probably become more complex once the laws are passed, with changing attitudes aiding enforcement and the enforcement of laws hastening attitude change.

cause people to drop out of that category; the rate does have a significant negative impact on the other measures of income, also as predicted. This negative impact is made up for by the higher coefficients associated with EEO enforcement variables in the equations for all workers and all those with income. For all those with earnings, for example, a cumulated dollar spent by the EEOC leads to more than a 3% increase in the income ratio. In parallel fashion, every ten or twelve favorable court decisions may be interpreted as

associated with a 1% increase in the income ratio, as may every 3,000 actionable charges.

Examining the earnings of all workers in the context of equation 1, we note that changes in educational levels since Title VII went into effect have been associated with a two and a quarter percent increase in the income ratio (coefficient of .16 times increase in the education ratio of 14%), while EEOC expenditures would be associated with a rise of 12%, everything else being equal (of course, everything

else was not equal, since the unemployment rate almost doubled in the interim). EEO enforcement activities appear to have had substantial impact.

The results for nonwhite women, presented in Table 3, are similar to those for nonwhite men. The proportion of variance explained is slightly greater, and nonwhite female incomes, unlike male incomes, seem to be sensitive in some cases to court decisions calculated on an annual basis. These possibilities must be treated very cautiously, however, because the

Durbin-Watson *d* statistics are in some cases in the range where serial correlation in the errors cannot be ruled out with a high degree of probability. It is also worth noting that the median total income of nonwhite women does not seem to be responsive to changes in the unemployment rate.

The results for white women presented in Table 4 provide some fairly dramatic contrasts with the findings for nonwhite men and women, and indicate that the utility of the hypotheses being tested is lim-

ited unless they are specified better. As shown in Figures 1, 2, and 3, white female incomes have declined relative to those of white men despite increases in the incidence of attitudes favorable to female labor force participation on an equal basis; in addition, the decline continued, at least for a while, in the face of legislative change and increasing EEO enforcement efforts. These facts are reflected in the coefficients, which are negative for public attitudes in every equation, and are negative or insignificant for EEO enforcement efforts in some of the equations. It may be

possible, however, that the reversal of the downward trend in total money income has been due to EEO enforcement activity. The coefficients for education remain strong and positive, as in Tables 2 and 3. Because relative white female education has been going down, declining incomes could be attributed to changes in relative education. Such an interpretation seems far-fetched, however, if only because initial white female educational levels were higher than those for men, while income levels hardly were.

In addition to the unexpected coeffi-

cients, the measures of R^2 and the Durbin-Watson d statistic indicate that there is something wrong with the model as it applied to white women. R^2 is notably lower in the equation for white women than it is for other groups. More significantly, the d statistic indicates the likely presence of substantial serial correlation in the error terms; such a result is often interpreted as an indication that important variables have been left out of the equation.¹⁷ A statistical model that worked reasonably well for nonwhites does not appear nearly as useful for explaining changes in the relative incomes of white women.

DISCUSSION

As expected, the unemployment rate generally has had a significant impact on the incomes of nonwhites. In addition, EEO enforcement activities have had a significant impact on their incomes. Unfortunately, the extremely high correlations between changes in attitudes and educational levels made it impossible to estimate their impacts separately; at this point, it is impossible to say how much of the change in nonwhite income has been due to each. The situation with regard to various measures of EEO enforcement activity is similar. Since the mid-1960s, improvements in nonwhite education, changes in attitudes and the law, and EEO enforcement activity all seem to form a historical "package." This collection of closely related forces has led to the improvement of nonwhite incomes, but it is difficult at a number of points to be very clear about the causal relationships among the variables or to gauge independent impact very precisely. The passage of time, providing more data points, the development of better measures of educational quality and attitude change, and studies at lower levels of aggregation may lead to analyses with statistically neater outcomes.

¹⁷ Generalized least-squares estimation could be used to overcome much of the effect of serial correlation, but in this context that would miss the point, which is that a particular statistical model derived from prior theoretical and empirical work does not work well when applied to a comparison of groups not hitherto examined.

The major problem raised by the findings has been the difference between the results for white women and those predicted for all groups and actually estimated for nonwhites. What kind of story could one tell that would explain the results and improve the specification of the model?

A great deal has been written about the similarities and differences between race and sex discrimination (for a general review, see Chafe, 1977: chaps. 3-4). There is no objective way to conclude which kind of discrimination is "worse"—although if one's standard is equality of results, sex discrimination seems worse because white women have lower incomes than nonwhite men, and nonwhite women have the lowest of all—nor is it possible at this stage to specify rigorously the relative difficulties to be overcome or the resources available to the different groups. Nevertheless, there are a number of factors, some operating before the passage of the laws, some built into the operation of the laws, and some occurring as a consequence, which can be described as making sex discrimination more difficult to overcome than race discrimination.

Among preexisting factors are the following: There is some evidence that labor market discrimination against women is "worse" than discrimination against nonwhites, in that income differences by race have been attributed largely to higher black levels of unemployment and restricted access to many occupations, while women suffer from these problems and from lower wages within job categories (Strauss and Horvath, 1976). Women may have had more education than men, on the average, but the education may have been less useful as women shied away from the acquisition of practical skills due to restrictions on their labor force activity (Madden, 1978). Women may be less unified in their interests than blacks, because the gains of some women may be at the expense of white men whose wives will suffer as a consequence (Alexis, 1974). Finally, white women may find it more difficult than nonwhites to make the same gains relative to white men simply because there are so many more white women; the changes in social struc-

ture implied by equal opportunity for white women are much greater than those implied by equal opportunity for blacks (Stern et al., 1976).

Thus, there are a number of preexisting factors that would make it more difficult for women to achieve equality. There are compensating factors, of course. Greater numbers can lead to greater political strength, if unity can be achieved, for example (Alexis, 1974), and white women can have the relatively easy access of white men to informal socialization, useful contacts, etc., when attitudes change. The empirical problem will be determining the net effect of each.

The law itself as it applies to women also makes their situation more difficult than that of nonwhites. Although historically both blacks and women have been subject to many legal restrictions on their activities, blacks have suffered from fewer legal disabilities than women since the mid-1960s. The differences are both constitutional and statutory. The Supreme Court has interpreted the Constitution so as to make race a "suspect classification"—laws that distinguish between races are inherently suspect, and will be struck down unless justified by a compelling state interest. Distinctions between the sexes have not attained this status, so arguments against sex discrimination rest on a shakier constitutional foundation than arguments against race discrimination (see Ginsburg, 1976; Getman, 1973).

Two major statutory issues have probably slowed the positive impact of EEO legislation on women. First, the relationship between Title VII and state protective legislation which limited certain labor force activities of women was initially unclear. It is now clear that Title VII overrides such legislation, but female progress was probably slowed somewhat by the uncertainty (see Gates, 1976). Second, as noted above, women can still be treated unequally in those cases where sex is a "bona fide occupational qualification" for a job; race is never considered a bona fide occupational qualification. Although the EEOC and the courts have tended to interpret this provision narrowly, it still provides a loophole in the law.

Finally, response to the laws may differ between groups, and it is in considering differential response that probably the most immediately useful way of dealing with white women is to be found.

The important variable is probably the rate of labor force participation. During the 1948–1975 period, rates of labor force participation among white women have increased considerably, rising from 33.3% in 1954 to 37.5% in 1964 and 45.4% in 1975. Given that a high proportion of the new entrants would have had few skills and little experience, it would not be surprising if the average earnings of all labor force participants went down, and that is what happened. If the elasticity of the supply of white female labor were high, and women were optimistic about opportunities increasing as a result of changes in legislation, the size of the influx of white women into the labor force could have outpaced the increase in opportunities, and continued to bring median earnings down even after the passage of EEO legislation. This picture would be consistent with the differences in trends in earnings as opposed to total money income described above (see Figures 1 and 2). The entry of inexperienced white women into the labor force could bring down the median earnings of those who are working, but increase the median total incomes of all women, since the earnings of the new entrants would go from zero to some higher figure. And, in fact, total money incomes have risen noticeably since 1963–64, even while median earnings continued to decline.

The situation has been quite different for nonwhite men and women. The labor force participation rates of nonwhite men have actually declined in recent years (like white male rates), going from 85.2% in 1954 to 70.3% in 1975, with most of the decline concentrated among older men. The participation rate of nonwhite women has been very stable; it was 46.1% in 1954, 48.5% in 1964, and 48.7% in 1975. For nonwhite men and women, therefore, changes in income due to EEO legislation and changing attitudes would be easier to detect because they would not be confounded with changes caused by trends in labor force participation.

This discussion raises an additional question, however. In response to what could be seen as increasing economic opportunities brought about by changing attitudes and legislation, white women increased their labor force participation, nonwhite women did not change theirs, and nonwhite men actually withdrew from the labor force. That is, each of the three groups in question reacted differently to changing circumstances.

A plausible partial explanation for the behavior of white women might be that they were the group with the most to gain from increased labor force participation in the short term. Their initial rate was lowest, so could increase most easily, and the initial level of education was high enough to promise better jobs than would be available to many nonwhites, whose educational level was lower. With regard to nonwhite women, it might be that increased opportunities for nonwhite men led some nonwhite women to drop out of the labor force, partly compensating for the arrival of new entrants. And, with lower educational levels to start with, new nonwhite entrants might have had less to gain than whites.

The model tested above fails when confronted with a group whose labor supply seems to be the most elastic of all groups considered, whose level of formal education was high, but whose labor force experience and practical training was low. It seems reasonable to hypothesize that the initial model and hypotheses about the impact of attitude change and EEO legislation would be supported by the evidence for all groups if the model were revised to include measures of labor force experience and actual skill levels. Alternatively, the model tested above should be supported once all other groups reach equilibrium levels of relative labor force participation and skills.

CONCLUSIONS

This paper has argued for the inclusion of changes in attitudes in the study of changes in the economic situation of women and nonwhites, for realism in the examination of laws' impact, and for comparing the economic status of all

groups protected by EEO legislation with white men, who are the criterion group in the legislation. The findings for nonwhites generally provide evidence consistent with the revised model, although it was impossible to test some hypotheses about the independent impact of variables because of multicollinearity. The model breaks down noticeably, however, when white women are considered, leading to the conclusion that it was improperly specified and should be revised to take labor force participation rates, work experience, and skill levels into account.

Although nonwhite men and women have made major gains relative to white men in recent years, and white women show some signs of reversing a downward trend, the income gaps between groups are still very large. The gains thus far may have been the easy ones, involving the elimination of especially crude and blatant forms of discrimination. As discrimination becomes more subtle, as structural discrimination becomes a more important part of total discrimination, and as the legal system is confronted more and more often with conflicts between fundamental values—such as nondiscrimination and affirmative action—further gains may become more difficult to achieve.¹⁸

ERRATA

The Items column in the February 1979 issue of the *REVIEW* (Vol. 44: p. 183) incorrectly identified the professional affiliations of J. Allen Whitt (*Towards a Class-Dialectical Model of Power*). Whitt holds a joint appointment in the Urban Studies Program and in the Department of Sociology at Brown University.

The final sentence of Robinson and Kelley's article, "Class As Conceived by Marx and Dahrendorf" (ASR February, 1979), contained an error. The correct version is: "For this reason we have taken this first step toward a merger of the class and status traditions."

THE VARIABILITY OF PARADIGMS IN THE PRODUCTION OF CULTURE: A COMPARISON OF THE ARTS AND SCIENCES*

REMI CLIGNET

Northwestern University

American Sociological Review 1979, Vol. 44 (June):392-409

While artistic and scientific endeavors take place in the context of collective actions, the structures and the functions of these actions are highly variable. The purpose of this paper is to show that the cohesiveness and permeability of culture producing communities differ *between* artistic and scientific fields as well as *across* the specific disciplines constitutive of each field, and that these contrasts are not stable over time. Correspondingly, the same variability characterizes the role played by paradigms in the definition of creative norms, in the rhetorics that professionals use to justify these norms, in the socialization of new practitioners and in the occurrence of scientific or esthetic revolutions.

Whether in the arts or the sciences individual creativity is embedded in the context of collective actions (Albrecht, 1968; Becker, 1974; Merton, 1973). This paradox results from the risks associated with the very publication of cultural works (Meyer, 1967). When artists and scientists innovate and depart from established conventions, they run the risk of being suspected of falsifying the documents offered to public scrutiny or of endangering the physical, emotional, and moral well-being of the society at large or of the professional communities to which they belong.¹

The purpose of the present paper is to identify the common and specific properties of the social processes regulating these risks. At first glance, the organizational patterns of artistic and scientific activities should be distinctive. The distinction between the unity of Truth and

the plurality of Beauty induces sociologists to use the singular form to label the study of science but the plural to label the study of the arts (sociology of science vs. sociology of the arts). Correspondingly, there should be differences *between* the social processes regulating the risks inherent in scientific and artistic endeavors.

Yet such differences are historically contingent. The accentuated division of labor which goes with urbanization and industrialization leads to a parallel segmentation of the relations that human beings establish with Nature and with their fellow human beings. This segmentation also fosters an internal differentiation of scientific and esthetic fields. Increased divergences in the definitions of biology and physics parallel increased divergences in the definitions of musical and literary worlds. As social arrangements become more complex, the word *discipline* ceases to refer exclusively to a diffuse form of social control, but evokes boundaries between specific arts or between specific sciences. In short, contrasts between the arts and the sciences do not preclude the possibility of contrasts *within* such fields.

On the other hand, culture producing communities are only subparts of the social system in which they are embedded. As such, they experience similar constraints in their attempts to control the raw materials needed for performing the relevant activities or to control the market places where individual works are

* Address all communications to: Remi Clignet; Department of Sociology; Northwestern University; Evanston, IL 60201.

I want to express my gratitude to Marshall Shumsky, Sam Gilmore, Karen Ribler, Andrew Weiss and Joe Valadez for their comments, but above all to Alvin Gouldner for his encouragements and his wisdom.

¹ The charges of heresy against Galileo or of obscenity against Stravinsky's *Rites of Spring* strongly suggest that creativity is often considered as a social problem. However professional communities do not only protect innovators against the negative social reactions generated by their work, but they also seek to prevent them from being discouraged by the apparent and/or temporary sterility of their investments.

presented to the public. These common constraints should limit the extent of differences between, as well as within, the organizational patterns of artistic and scientific communities.

In summary, the interplay of internal and external forces makes equally plausible the possibility of divergences and convergences in the organizational structures of specific disciplines in the arts and the sciences. Correspondingly, comparisons between these two fields require appropriate functional and historical controls. Overall parallels or contrasts between cultural worlds should not mask their internal variability, nor should they be viewed in a temporal vacuum. Similarities and dissimilarities between specific esthetic or scientific disciplines cannot be constant since their respective profiles have a history which is itself dependent upon the history of larger societies.

The Notion of Paradigm in the Arts and the Sciences

The first step of the analysis consists in evaluating the possibility of applying the notion of *paradigm* to the various art worlds, since this notion initially has been used solely to describe the universe of scientists. Basically, the term refers to two qualities shared by few works. These works represent a sufficiently unprecedented achievement to attract a group of practitioners away from competing modes of scientific activity, but they also remain sufficiently open to leave all sorts of problems for the redefined group of practitioners to solve (Kuhn, 1970:10).

Popular stereotypes suggest substantial differences between such a world and the organization of artistic activities. They stress the marginality of artists who are entitled to behave like Robinson Crusoe in their enterprises and whose achievements do not require their participation in "invisible colleges" (Ziman, 1968:10). Yet, even at the peak of the individualistic ideology which accompanied Romanticism, Baudelaire complained that the "present state of painting is the result of an anarchic freedom which glorifies the individual, however feeble he may be, at the ex-

pense of schools which are nothing but the organization of inventive forces" (Pelles, 1963:96). About the same time, Constable also argued that "painting is a science in which canvases are the experiments" (Pelles, 1963). Thus, artists themselves suggest that their activities, too, are negotiated in the context of institutional and of informal arrangements. But are the paradigms underlying sciences and the arts serving similar functions and are the corresponding parallels constant over time?

Because the functions performed by paradigms depend upon their structures, the next step consists in evaluating how technological innovations and changes in the relevant markets introduce new modes of differentiation both between and within artistic and scientific worlds. These external forces alter the membership of creative communities, their modes of division of labor, and hence the relations of cooperation and competition among individual practitioners. Thus, the structures of distinctive artistic and scientific disciplines may have varying levels of cohesiveness and permeability.

Yet, the notion of paradigm remains multifaceted (Masterman, 1970). To the extent that it represents a common definition of achievement, it is a political institution whose function is to identify individuals whose works meet the appropriate standards and to regulate their professional lives. At the same time, this identification rests upon a normative definition of the tasks to be accomplished and of the techniques to be used to that effect. Thus, the word *paradigm* carries distinctive connotations such as "changing boundaries between truths and errors," "successful metaphysical speculations," "models," "analogies," etc., but also "standard illustrations," "accepted devices," and finally "normal activity." The last step of our analysis consists therefore of showing how the differential structures of creative communities are associated with parallel contrasts in: (a) the common assumptions underlying the definition of the tasks to be accomplished, of the techniques to be used and of the publication of the work so produced; (b) the allocation of rewards to practitioners; (c) the modes of

socialization of new members; and (d) the boundaries between normal and revolutionary practices. To examine the various facets of the notion of paradigm should indeed help to distinguish normal sciences or arts from scientific or esthetic revolutions.

A Comparative View of the Structures of Artistic and Scientific Paradigms

The internal cohesiveness of paradigms depends upon the technology used to *produce* and *publish* cultural works. As long as the technology of production retained a low level of complexity, major boundaries separated craftsmen from scholars rather than artists from scientists. In Europe, the world of craftsmen initially was characterized by a marked division of labor and a corresponding hierarchy of occupational roles; but contemporary scholarly communities shared an individualistic ideology and an intellectualistic disdain for the irrationality of manual work.

In contrast to sculpture which [was] only a *craft*, because it must be learned from a teacher and involves physical fatigue, painting [was] an *art*, since it require[d] a knowledge of theory and of all the noble sciences that can be mastered without a teacher. (Paggi as quoted by Wittkover and Wittkover, 1968:11)

At the same time, artists and scientists were equally devoted to the identification of the "diagonals" crossing the mineral, vegetal, animal and cosmic orders (Caillois, 1960). Thus, Leonardo was only one of the many scholars to pass freely back and forth between artistic and scientific enterprises; the study of anatomy equally attracted painters and medical doctors (Kuhn, 1970:161; De Santillana, 1959:39-45).

Increased innovations in the technology of scientific and artistic production have marked the end of the premium attached to scholarly versatility (Kubler, 1962). Gone are the days when Jefferson could successfully dabble in architecture and in scientific ventures. Further, these innovations have had diverging effects on the sciences and the arts. Technological innovation has been uniformly conducive to a

spatial concentration of scientific communities and to a growing segregation of amateurs and professionals. The production of science has invariably moved into capital-intensive, large-scale organizations. Yet, this move did not simultaneously affect all scientific disciplines; physics has evolved before biology in this regard.

In contrast, the effects of such innovations on the arts have been more *diversified*. The invention of paint tubes has facilitated a dispersion of artists, a lowering in their modes of division of labor, a blurring of the distinction between apprentices and masters or between amateurs and professionals and a broadening of the objects deemed to be esthetically valid.

In music, the mass production of musical instruments has made it possible to enhance the variability of the syntactic properties of differing genres and more specifically, the range of interactions between the number and the autonomy of the organizational patterns (the frequency of the sounds used, the pitches, the rhythms, etc.) used by composers (Attali, 1977; Hennion and Vignolle, 1975; Loesser, 1954). This variability has accentuated tensions between the various categories of actors present in the musical scene. Thus, after the beginning of the nineteenth century, the performance of a score became as much an opportunity for musicians to display their own skills as to remain the modest servants of composers (Sennett, 1977).

Finally, changes in cinematographic technology have been associated with a parallel concentration of the corresponding paradigms. The formation of the first stylistically unified paradigms such as expressionism or neorealism has occurred first in countries such as Germany and Italy where the effects of increasingly rationalized means of cinematographic production were amplified by a favorable political ideology (Huaco, 1965:18-22). The subsequent systematization of these paradigms is evident in the increased number of explicit references that a director makes to plots or techniques used by illustrious predecessors. *We Loved Each Other So Much*, the film of Scola,

includes a double narrative, one concerned with a specific plot, the other with the history of the cinema in Italy.²

Alternatively, innovations in the technology of communication have uniformly modified the forms taken by the internal cohesiveness of culture producing communities. Because the mass reproduction of visual or acoustic statements has lowered the need of face-to-face contacts among practitioners, their communities have been increasingly based upon the sharing of common values rather than on the sharing of the same space. Secondly, these innovations have enlarged the problems treated by the members of each cultural discipline through a refinement of the evidences deemed to be socially acceptable (Ivins, 1969:160-3). Last, they have modified internal patterns of division of labor and hence the relations of cooperation and competition among individual practitioners.

However, the effects of these innovations on various disciplines are not necessarily simultaneous. Revolutions in the techniques of lithography and engraving and later of photography may have produced more differentiated images of reality; yet, in order to be used such images had to be consistent with the assumptions of each field. As an example, the testing of Einstein's theories on relativity by photographic evidences obtained during the solar eclipse of 1919 required first the community of physicists to assess the validity of the data created and hence to create theories to deal adequately with the methodological problems raised by their use (Moyers, forthcoming).

The same holds true of the visual arts. Change in the techniques of engraving have modified the boundaries between arts and crafts.³ Certain derivations of

these techniques aimed at improving the *reproduction* of esthetic artifacts, others at the *creation* of new esthetic objects (Ivins, 1969: chap. 4). The consequences of the invention of photography have been analogous. Liberating painters from the obligation of making portraits, a genre which was deemed to be minor, photography has enabled artists to explore new esthetic problems, at the risk of making the definition of their public more problematic (Ivins, 1969; Freund, 1974; Renoir, 1960). At the same time, the definition of photography itself also has been increasingly differentiated: it has become both a documentary technique and an autonomous art form (Rosenblum, 1978; Sonntag, 1977).

Although the introduction of mass reproduced recordings has occurred later, its effect on musical communities has been analogous. Performers are no longer obliged to share a common knowledge of musical notations and to undergo the same type of musical training. In this sense they are able to form autonomous musical communities (Bennett, 1972). Further, their communities are increasingly specialized. Some of them are exclusively turned toward recording activities, others remain in direct contact with the public. At the same time, this innovation also has accentuated competition among artists through a systematic refinement of the social definition of ideal sounds (Drees-Ruttencutter, 1977; Sennett, 1977).

The permeability of artistic and scientific communities to external influences varies with the complexity of the patterns of social stratification operating in the society at large. Up to the seventeenth century the subordination of artists and scientists to their clients minimized the distinction between pure and applied forms of the corresponding forms of activity. Thus during his life time, Kepler owed his fame as much to his endeavors as an astrologer as to his astronomical computations (Bronowski, 1956:15). In painting, patrons influenced the definition of the scenes to be depicted, of the colors

² For a full description see Seitz (1977-1978) and Copeland (1977). More generally, modern artists finding themselves with no shared tradition, tend to build on older works of art.

³ To state that "academic art" marks the turning of art into craft (Becker, 1978:878) is to fall prey to an error of paralogics. The value judgments passed in this regard by the "creators" of a particular society or period, by their contemporaries and by the posterity are based upon distinctive criteria. Further, the external and internal forces that lead a work to be

shifted from the category *art* into the category *craft* or vice versa differ both across times and across disciplines.

to be used and of the size of the canvases. Salvator Rosa (1615–1673) was one of the first painters to assert that he was “painting for his own satisfaction and pleasure rather than to please his clients” but to be disappointed by the discordances between his own evaluation of his canvases and the tastes of his buyers (Haskell, 1963:23).

Changes in the modes of division of labor at work, in the society at large and in the corresponding patterns of social stratification, have enabled artists and scientists to increase their social autonomy through the institutionalization of academies (Pevsner, 1940). Initially, however, the effectiveness of these efforts varied across societies. Differences between the relative centralization of French and British political and economic structures during the seventeenth and eighteenth centuries were associated with parallel contrasts in the nature of local academies, in the social background of local artists and scientists, in the interindividual variability of the definitions of tasks to be accomplished and in the stratification at work in the creative professions (Shapin and Thackeray, 1974; Pelles, 1963; White and White, 1965). In short, the extent of initial cultural variations in the insulation of creative communities reveals the importance of the influence exerted by external factors on their functioning.

With the later systematic development of industrial organizations and urban centers, the growing segmentation of social groups, and the corresponding decline of “public life” have uniformly enlarged the social distance separating scientific and artistic communities from one another and from their respective followers (Grana, 1964). Yet the effects of this increased insulation have differed between the two fields. The continuous concern of industrial societies about progress, and the corresponding fusion of science and technology have enhanced the autonomy of scientific social systems (Lammers, 1974:126). Since the nineteenth century, laymen are said to stand in awe of scientists because they do not understand their work, but to despise artists for the same reasons. Unduly modest in the first case, the “philistine” is unduly conceited in the second

one (Kuhn, 1969:406; Getzels and Csikszentmihalyi, 1976; Sennett, 1977).⁴

Such contrasts *between* the arts and the sciences should not mask the processes of differentiation that have taken place *within* the two fields. First, both of them are subjected to the tensions resulting from the distinction between *pure* and *applied*. The participation of scientists in applied ventures has been and still is considered to be sufficiently debasing to jeopardize their status in their scientific community of origin (Kevles, 1977). The same tensions characterize the arts and particularly those which involve several media. Even though the famous conductor Ansermet asked the dancer Margot Fonteyn whether she approved the pace he had adopted, the fact remains that a successful young conductor recently left the Royal English Ballet because it was too risky for his career as a conductor (Rockwell, 1976).

In addition, culture producing fields tend to be similarly differentiated in terms of the participation of the public in the definition of the problems to be treated. Lay images play a more significant role in the origin, the elaboration, and the diffusion of key concepts in the social than in the natural sciences (Hudson, 1972; Lammers, 1974:136–40). The same holds true in the case of the scientific disciplines involved in the study of environmental impacts as compared with those directly concerned with the production of new materials (Schnaiberg, 1977). As a result, both social and “impact” sciences encounter more criticisms and are more vulnerable to external pressures. In the same way, variations in the mechanisms by which movie makers, musicians and painters establish contacts with their audiences are associated with concomitant contrasts in the social importance attached to the “veridicality of their statements” (Becker and Walton, 1976).

Thus at one end of the continuum, pressures toward “veridicality” remain high

⁴ As suggested by Sennett, the philistine may entertain some doubt about the validity of his skepticism whose intensity and assertiveness vary across esthetic fields.

in the case of the cinema and of music. Because of the amorphous nature of cinematographic audiences, veridicality requires cinematographic statements and symbols to be plausible and hence held acceptable by various social groups.⁵ Similarly, in music, veridicality implies familiarity and hence the desire of performers and audiences alike to *recognize* the statements which are to be played. The organizational constraints experienced by orchestras as a result of the homogeneity of their past-oriented audiences force conductors either to retain a conservative repertoire or to look for new audiences⁶ (Zolberg, n.d.). It is only in the case of the visual arts at the other end of the continuum, that pressures toward veridicality are both lower and more diversified. The democratization of means of pictorial production, the loss of the monopoly initially enjoyed by academies on the sale of canvases and the development of private galleries have facilitated an early segmentation of paradigms. This segmentation has been accentuated, later on, under the combined influence of two additional forces. In ideological terms, the notion of veridicality has been undermined by the partial legitimation of the concept of the *avant garde*⁷ (Poggioli, 1971; Baudrillard, 1972). In material

terms, the same notion also has been undermined by the faster turnover of canvases in art markets and by the progressive erosion of the differential acquisition policies adopted by private collectors or galleries as opposed to public museums.⁸ Indeed both public and private sectors have become evenly sensitive to the charges of serving the interests of esthetic forms deemed to be obsolescent.

In summary, changes in technology and in market structures have been associated with a progressive differentiation of communities both *between* and *within* cultural worlds. Contrasts in the internal cohesiveness or the permeability of specific disciplines induce parallel variations in the tensions between the behaviors of cooperation and competition adopted by the relevant types of practitioners.⁹ At one end of the continuum, both the low patterns of division of labor of certain of these disciplines and the accentuated segmentation of their audiences facilitate the coexistence of distinctive paradigms. In fact, common sense acknowledges the ideological nature of the commitment attached to such paradigms by using the suffix *ism* in their definition. The functionalism, Marxism or symbolic interactionism of sociology or the behaviorism of psychology correspond to the pointillism, fauvism, or tachism of painting or to the naturalism, symbolism or surrealism of literature. In the middle of the continuum, music is characterized by the coexistence of several independent paradigms (tonal and atonal music) within which practitioners adhere to a set of more rigid rules. At the opposite end of the continuum, physical scientists solve the tensions between their faith in a past-oriented orthodoxy and their commitment to a future-oriented "revolution," by shifting their profes-

⁵ In the cinema as in other mass media, statements exploring individual psychological traits are suspect whenever such traits can be imputed to an easily identifiable category of the population. The reactions of certain critics to *Nightporter*, the film of Cavani, offer a case in point. In spite of the explicit statements made by the director, her exploration of a pathological relation between one aggressor and his victim was deemed to be a generalized portrait of the behaviors and feelings of the entire population of former concentration camp inmates (Cavani, 1974).

⁶ Given the fact that live composers are confronted with dead audiences (see Mayer, 1975), a number of contemporary musicians seek to attract a new type of audience. Shapey offers to critics the scores of the pieces he is going to perform. Boulez and Poliakoff allow their audiences to wander from room to room or to sprawl on comfortable rugs.

⁷ Indeed this legitimation is only partial. This means that there are significant contrasts in the importance that distinctive groups of patrons attach to the "veridicality" of a pictorial statement. As a matter of fact, an innovation in the arts does not mean that preceding works are disregarded (Ackerman, 1969: 372).

⁸ The erosion of such differences is partly due to the spectacular rises in the merchant value of old paintings which have driven out museums from the relevant markets (Reitlinger, 1961:70).

⁹ If the production of culture depends upon relations of cooperation, both this production and its evaluation also depend upon the application of specific norms by significant others to each work and its author. In this sense, culture producing worlds are dominated by power relations (Griffin and Griffin, 1976:175-6).

sional allegiance rather than by changing the labels used to describe their activity (Leighninger, 1976).

Variations in the relative dominance of one single paradigm in distinctive artistic or scientific disciplines are associated with parallel contrasts not only in the membership of the corresponding communities but also in the nature of their norms and in the actual behaviors of individual practitioners.

A Comparative View of Artistic and Scientific Paradigms As Shared Values

Cultural endeavors rest upon a common metaphysical belief in the possibility to overcome the accidental. Yet, there are variations in the basic underlying assumptions. Scientists tend to aim at interpreting events in terms of the most consistent generalizations. Artists search for symbols which translate most effectively the nature and functions of things into individual experiences (Arnheim, 1966:18-37; Barzun, 1974:25). Correspondingly, there should be contrasts both in the norms of the two fields and in the rhetorical styles used in the publication of individual works. However, such contrasts are historically relative and tend to be as significant within as between such fields.

(1) *A comparison of artistic and scientific norms.* The notion of paradigm presupposes conformity to a set of norms regulating the conditions under which individual contributions should enhance the collective capital of knowledge. The significance of these contributions is *uniformly* a function of the validity imputed to underlying theories and methodologies. In science, the evaluation of new theories in astronomy has successively required the acceptance of the evidences produced by the use of telescopes and photography (Feyerabend, 1975). Similarly the validity attached to esthetic substance is not independent of the validity attached to style. Changes in the objects deemed to be worth painting (landscapes, portraits, etc.) and in the methodological rules underlying their translation (e.g., the construction of space or the use of colors) tend to follow parallel patterns (Francastel, 1970). In literature, changes

in the plot of novels are often conducive to change in the tenses or pronouns deemed to be stylistically most effective (Barthes, 1953; Goldmann, 1964; Lukács, 1971).

Regardless of these interactions between theories and methodologies, the formal evaluation of individual contributions also presupposes a set of conventions underlying the publication of cultural works. In both cases, practitioners must believe in the merits of a system of beliefs articulated around the norms of universalism, organized skepticism, communism and disinterestedness (Merton, 1973; Mitroff, 1974; Krohn, 1977).

Yet, the meaning of the norms of universalism and organized skepticism remains relative. The differential nature of esthetic and scientific generalizations induces concomitant variations in the significance attached to the requirement of *reproducibility*. Because the validity attributed to a scientific theory depends on the replication of its findings by other scientists, scientific experiments must include a full presentation of the procedures followed, and of the results obtained; they must also be void of deliberate falsification. It is only under these conditions that current theories can be "falsified."¹⁰ In contrast, as exemplified by the *Venus of Milo*, the unfinished novel of Stendhal, *Lucien Leuwen*, or the unfinished movie of S. M. Eisenstein, *Que Viva Mexico*, works of art may become exemplars, as such subject to further testing, even when they are partially destroyed or incomplete. Further, esthetic forgery is not necessarily viewed as a sin by artists or by patrons, and Renoir, for example, allowed himself to correct and sign canvases painted by impostors (Renoir, 1960:185).¹¹

However, the stress placed upon the reproducibility of results also varies across scientific disciplines and its salience depends on the ease with which the prob-

¹⁰ It is interesting to note that to falsify scientific evidences is a vice, but that to falsify scientific theories is a virtue.

¹¹ Leger is supposed to have forged some Corots and Vlaminck some Cezannes. Further, the buyer of a Modigliani canvas painted by Elmyr decided after all to keep the painting as long as he was assured that the forgery was indeed the work of Elmyr (Irving, 1969).

lems deemed to be crucial are defined (Mitroff, 1974:592-3). Whereas conventional norms are dominant for well-structured problems, a set of counter-norms appear to be dominant for their ill-structured counterparts. As an illustration, the experiments conducted on the composition of lunar soil followed clear-cut procedures, but the rules of evidence adopted to identify the origin of such a soil were much more problematic. Further, the stress placed upon reproducibility also varies within the same discipline. In psychology for instance, the norms cannot be the same in the case of learning theories which maximize the principle of *proof* as in the case of psychoanalysis which maximizes the principle of *consistency* (White, forthcoming). Finally, this stress is minimal in those scientific fields that do not establish clear-cut distinctions between ideological and scientific statements or between externally and internally induced statements (Gouldner, 1976). As an example, the avoidance taboos that anthropologists display towards one another's tribes violate the principle of reproducibility.

In contrast to appearances, however, the notion of reproducibility is not totally absent either from artistic fields. Its significance is maximal in the case of the performing arts where it has grown as a result of the increased differentiation between composers and performers. Thus, the conflicts experienced by Romantic musicians between an ideology of progress and glorification of the past have made the notion of interpretation more problematic. Emphasized by certain Romantic composers, the obligation of playing partitions the very way they have been written by their authors has been criticized by contemporaries of Schuman, mocked by Satie, and more or less abandoned by modern composers such as Cage (Sennett, 1977:198-201). But like scientists, writers or painters also use reproducibility to test the limits of the most significant statements of their predecessors. In *Antigone*, Anouilh aimed at identifying the limits of the plot originally written by Sophocles. In many of his canvases, Cezanne sought to test the tectonic order sketched by Poussin (Kubler,

1962:87). Yet, because subjectivity is socially more acceptable in the arts than in the sciences, there are more significant interindividual variations in the form or the extent of the materials or techniques borrowed from the esthetic than from the scientific "Eminent Domain" (Ellmann, 1967; Maison, 1960; Meyer, 1967).

A comparative analysis of conformity to the norms of communism and disinterestedness across culture producing fields yields similarly fuzzy results. On the one hand, the publication of scientific works is presumably more economically gratuitous than that of esthetic endeavors. But because scientific rewards are hence essentially symbolic, the notion of priority is more value-ridden and conflict producing in the sciences. Charges of plagiarism are more extensively defined and sanctioned in the corresponding communities. On the other hand, the distinction between pure and applied entails uniform consequences in the privileges attached to certain types of artistic and scientific communications. The world of patents parallels the world of royalties, copyrights, and residuals.¹² Similarly, in spite of the obligation of sharing the fruits of their experiences, many artists and scientists delay publication, either to increase the rewards to which they aspire, or to eliminate potential sources of opposition. Their behavior in this regard varies both with their seniority and the stratification structure of their discipline (Sullivan, 1975:229-44). Newton's ideas on optics were thus published after the death of Hooke, his chief opponent on the topic (Nicholson, 1946:11-3). Similarly, Anais Nin waited until the end of her career before publishing *The Delta of Venus*, a piece of erotica which would have jeopardized her fame, had she published it earlier.

In both cases, conformity to norms and counternorms facilitate an identification of exemplars. In both cases, this identification induces a tendency to see the past develop linearly toward the current vantage point and partly by selection, partly by distortion, to view the work of signifi-

¹² It should be noted in this regard that the rights of musicians and actors are better protected than those of painters.

cant predecessors as abiding to the rules legitimized by the most recent revolutions (Merton, 1973; T. S. Elliott, as quoted by Kubler, 1962:35).

However, the time orientations underlying the definition of these exemplars vary both between and within artistic and scientific fields. In contrast to the visual and literary arts, the progress and hence future-oriented ideology of the "hard" sciences has always condemned theories proven false to immediate obsolescence (Polanyi, 1958:194). In this sense, scientific exemplars serve more demanding functions than their esthetic counterparts, but their life span is also shorter.

Yet, in both fields, the duration of exemplars depends upon the tensions between normal and revolutionary practices. To assert that scientific exemplars do not necessarily produce drastic changes in the outlook of the disciplines is merely to give preeminence to "normal" over "revolutionary" practices (Polanyi, 1958:220). Alternatively, to complain about the invalidity of the equation between older and better (Feyerabend, 1975) or to associate exemplars with the discoveries of new theories (Meyer, 1974) is to stress the preeminence of scientific revolutions. The same tensions characterize contemporary arts and literature. Whereas literary and artistic exemplars used to be defined in terms of jurisprudential precedents, the legitimation of the notion of avant garde induces a growing number of art connoisseurs to equate old with obsolescent (Baudrillard, 1972). "Art collectors must be taught how to throw works of art in the garbage can as they do refrigerators or cars when new models come on the market" (as quoted by Moulin, 1976:64).

Last, the life cycle of exemplars varies with the permeability of the various culture producing disciplines to external influences. In the physical sciences, the visibility of an exemplar remains constant as long as it has not been successfully challenged. In other words, boundaries between its life and its death are clear-cut. In contrast, the contribution of lay images to the formulation of the problems central to the social sciences or to the literary, musical or other artistic disciplines renders the life cycle of the relevant exemplars more

problematic. Indeed such life cycles often follow curvilinear patterns¹³ (Panofski, 1965; Haskell, 1976; Kubler, 1962). Thus, the current interest in sociobiology has induced a "renaissance" of the researches undertaken earlier by Spencer. In music, Vivaldi's music fell into oblivion until its rediscovery by Pincherle and Witold in the early 1950s. Finally, the extreme permeability of the performing arts to external influences enhances the fragility of the relevant exemplars. A play which has not been performed at the time of its conception or has been a failure is unlikely to be staged when it is rediscovered. Similarly, exemplars in methods of acting rarely survive the life time of their inventors.¹⁴

(2) *A comparison of artistic and scientific rhetorics.* The differential nature of artistic and scientific generalizations implies parallel contrasts in the languages used by the two types of practitioners (Hofstadter, 1955; Bronowski, 1956; Werner, 1975). However, these contrasts vary necessarily with the historically contingent conceptions that creative communities have of their audiences. Because of the requirement of reproducibility in the sciences, "scientific statements" are expected to reach out for materials beyond the self-contained confines of their own products and to begin with an overview of the conclusions which can be derived from the appropriate literature (Gusfield, 1976). For this reason, scientific demonstrations emphasize as much the *how* as the *what*. Yet the stress upon the *how* is also apparent in esthetic communities. Art galleries and museums often offer a highly structured catalog to their visitors. Similarly classical plays used to treat commonly known problems in order to enhance the visibility of the skills dis-

¹³ Thus, it is simply not true that the price of a painting is directly (positively or negatively) related to its age (Becker and Walton, 1976). In fact, this relationship takes a variety of forms and may follow curvilinear or threshold patterns (Reitinger, 1961; Robertson, 1970). In addition, these patterns seem to be subjected to an acceleration. Thus the "rediscovery" of eighteenth century painting took about a hundred years, whereas it took only fifty years for Art Deco to enjoy a renewed popularity (Moulin, 1976:78).

¹⁴ The case of Stanilawski offers an exception to this pattern.

played by their authors. Finally, it is because the public and the actors of the eighteenth century shared the same knowledge of the plays performed, that the latter aspired to repeat the lines most appreciated by their audiences (Sennett, 1977:77).

Secondly, in contrast to artistic style, scientific rhetoric is expected to be devoid of subjective touches and to emphasize the external nature of reality. Both scientific and esthetic rhetorics are nevertheless criss-crossed by conflicting currents in this regard. In general terms, the scientific vocabulary includes esthetic terms. Thus "the structure of the DNA was too pretty not to be true" (Watson, 1968:80, 105, 136). In addition, terms such as *findings*, *inventions*, *discoveries* suggest that Nature precedes human activity; but terms such as *creations* and *designs* remind us that technology, offering syntheses which satisfy functional requirements, breaks the "windowpane" which separates scientists from the outside world (Simon, 1969:55). Symmetrically, in the arts, the image of artists as creators competes with the image of artists as mere witnesses of the superior beauties created by Nature. In the context of this latter tradition which ranges from artists of Ancient Greece and China to Duchamp, the signs traced by Nature on leaves, driftwood or rocks represent the most advanced form of art; the major responsibility of artists is to make them available to the public (Caillois, 1960:54-68). In short, the rhetorics that minimize active human inputs in the creation of events cut across all fields.

Thirdly, the professional insulation of artistic and scientific communities introduces similar tensions in their respective rhetorics. All fields experience conflicts between *showing* (when the author avoids claims of authority) and *telling* (when he derives his assertions from his expertise). The resolution of these conflicts depends both upon the history of each field and its rank order in the hierarchy of the disciplines. The relative preeminence of "showing" in the use of mathematical formulas by social scientists reflects the higher status accorded to mathematics (Whitley, 1977:143-70). Similarly, the

high status enjoyed by scientists in the nineteenth century induced artists to borrow elements of a scientific rhetoric. Flaubert compared his activity as a novelist with that of a surgeon probing the soul of his characters.

Finally, the increased differentiation of artistic and scientific paradigms raises similar problems with regard to the identification of appropriate audiences. In sociomedical studies, articles about drinking as a social problem appear most frequently in the *Quarterly Journal of Studies on Alcohol* (Gusfield, 1976:19). In the same vein, Broadway, off-Broadway and off off-Broadway refer simultaneously to differing theatrical styles and differing theater houses. In more general terms, the choice of a rhetoric appropriate to an audience whose properties are increasingly elusive, raises similar difficulties in the social sciences and the arts. In both cases, these difficulties reflect the changing boundaries between insiders and outsiders, and hence between practitioners and the "objects" of their researches (Merton, 1973). In this regard there are marked parallels between the history of black or women's art and the history of black and women's studies. Black social scientists and black artists were obliged to use a white-dominated "universalistic" ideology, as long as their survival was exclusively dependent upon the good will of a white cultural elite (Rosenberg, 1977). In the same vein, the assertion that a woman's art presents traits that are inaccessible to a male audience (as quoted by Glueck, 1977:66) requires the development of specialized galleries entitled to cater to the needs of a specialized audience of insiders.¹⁵

A Comparison of Artistic and Scientific Paradigms As Systems of Rewards

Both the norms and the rhetorics characteristic of a particular paradigm constitute justifications of the processes underlying the identification of successful indi-

¹⁵ It is possible, however, to speculate as to whether "women's art" in this regard is not condemned to experience the same fate as regional or populist stylistic forms, successes of which have been short-lived.

viduals. As the autonomy and the cohesiveness of culture producing communities evolve in differing directions, there are increased contrasts in the organization of their respective reward systems. As a result, the form, the object, the timing, and the consequences of the tensions generated by the identification of successful individuals vary across specific disciplines as well as over time.

As a discipline is dominated by one single paradigm, the identification of successful practitioners tends to occur within the community itself and the ensuing tensions oppose insiders to one another. Conversely, among these fields split by a variety of paradigms, it is customary to differentiate those individuals who are recognized by their peers from those who obtain a commercial success. In other words, the allocation of rewards tends to generate internal wars in the first case, but both internal and external wars in the second one. In addition, the greater the domination of one single paradigm in a discipline, the greater the likelihood that the tensions will pertain to the priorities of discoveries and hence to the charges of plagiarism. In contrast, among those fields split by a variety of paradigms, conflicts will more often pertain to the relative originality of competing statements. Finally, the more a discipline is dominated by one single paradigm, the shorter tends to be the lapse of time evolving between the publication of a work and the public recognition of its qualities. Thus, posthumous recognition is an oddity in the natural sciences, since the worth imputed to a scientific work is a function of its immediate contribution to existing theories.¹⁶ In contrast, the "careers" of works in the arts or the social sciences follow more complex patterns; Stendhal, for example, knew that his success would not be immediate when he dedicated the *Red and the Black* to the "happy few."

Secondly, the opportunities enjoyed by individual practitioners depend upon the developments of their field and its permeability to external forces. Indeed, while creative personalities differ from one an-

other in terms of their qualities of obsessiveness, versatility, evangelism, rebelliousness or avant gardism (Kubler, 1962), the rewards derived from such qualities vary with the problems deemed to be crucial in each field.

At any one point in time, practitioners tend therefore to migrate toward activities which offer greater opportunities. These migrations reflect the combination of three conditions: (1) both disciplines must be considered to be professional; (2) the field of destination must be rank ordered lower than the field of origin; (3) the former must however be characterized by less competition than the latter. At one single point in time, professional migrations tend therefore to be unidirectional. Thus the development of experimental psychology required the mobility of high status physiologists toward the less competitive field of philosophy, of which psychology was initially only a specialty (Ben-David and Collins, 1966:465). Similar patterns may be more casually identified as far as the arts are concerned. The renewal of religious decorations of tapestries or of ceramics was facilitated by the migrations of painters such as Matisse, Leger, Rouault, Cocteau and Picasso toward the corresponding disciplines. In the same vein, the renewal of the French theater after World War II has been stimulated by the invasion of novelists such as Sartre or Camus.¹⁷

Third, even though the "Matthew effect" arbitrarily enhances the visibility of the contributions made by senior artists or scientists, its power varies across disciplines. It is for example, lower in biology than in physics (Allison and Stewart, 1974:602). This is because biology is characterized by a low consensus over issues of theory and methodology, does not have a core system of communications, and does not facilitate the intergration of prac-

¹⁶ The work of Mendel in genetics stands of course as an exception to this general pattern.

¹⁷ The argument could be expanded to other fields. Thus, French writers have invaded the field of lyricists and French painters such as Picasso have designed posters. In contrast, it is difficult for lyricists to be acclaimed as poets or novelists or for poster designers to acquire fame as painters. In more general terms, then, it is easier for artists to invade the world of craftsmen than for craftsmen to be labelled artists. Hence potters who want to be treated as artists will relabel themselves as ceramists.

tioners in single organizations. By analogy, it is possible to suspect that the Matthew effect is more powerful in the musical domain than in the art world. As already noted, the first discipline remains more integrated than the second one.

Last, individual careers depend upon the control that each discipline exerts upon the two major scarcities represented by access to the relevant raw materials and to the public. The greater this control, the greater the prestige attached to teaching which becomes the ultimate reward accorded to successful practitioners. Architecture, medicine or theater offer as many cases in point because the relations of sponsorship prevailing in such disciplines enable professors to select their best students and control the progress of their careers. Conversely, painters and writers cease to teach as soon as they are sufficiently successful. This is because the segmentation of the relevant markets and the dispersion of the means of esthetic production prevent the most successful practitioners from controlling the careers of newcomers. Thus Sartre ceased to teach as soon as his talent as a writer was sufficiently established. Similarly Matisse is the last great painter to have unsuccessfully tried to open a school.

A Comparison of the Socialization Functions of Artistic and Scientific Paradigms

Even though all communities are necessarily concerned with the social integration of newcomers, the form, the stability, and the instruments of socialization vary not only with the number of paradigms dividing each discipline but also with the ideological orientations accompanying the corresponding plurality.

Hard science communities tend to establish clear-cut distinctions between truths and errors. Because of their professed rationality, and of their ahistorical orientations, they reject as inappropriate for professional scrutiny, theories and techniques held to be erroneous. In other words, the invisibility of scientific revolutions results from the continuous elimination from the appropriate textbooks of all materials that have become obsolete. In

contrast, the polyparadigmatic nature of the social sciences or the arts makes the relevant instruments of socialization more durable. Museums and libraries seem to play a more important role in the training of artists or social scientists than of physicists or chemists (Kuhn, 1970:167).¹⁸

Yet this overall contrast should not mask differences in the ideological relations that each discipline establishes between its own time orientation and its differentiation of a high versus a low or a professional versus an amateur culture. Indeed, various disciplines do not experience the same types of tensions in the way they use the past, the present and the future in their evaluation of a particular work. Nor do they use similar criteria for defining the hierarchy of the tasks to be mastered by individual practitioners. Nor do they establish similarly strong connections between these two dimensions.

The greater the salience of such connections, the greater the stability of the sequential order in which the various components of the relevant curricula are presented to students. There are increasingly sharp contrasts in this regard between the modes of socialization used by scientific and musical communities on the one hand and by fine art schools on the other. In spite of their future orientations, scientific communities continue to teach first how to deal with "obsolete" problems such as inclined planes, conical pendulums, and it is only later in the sequence that newcomers learn how to deal with the symbolic generalizations currently shared by professional physicists. In short, the apprentice must first master the wisdom collectively accumulated by the profession before being allowed to undertake future-oriented research activities (Kuhn, 1970:47; 139). To a certain extent, patterns of musical socialization retain a similarly stable sequence involving the initial mastering of historically stable techniques

¹⁸ Of course, the importance attached to such institution in the context of the arts and the social sciences depends upon the time orientations attached to specific paradigms. The more ahistorical schools of thought in sociology tend to regard the teaching of classical theories as having little significance and prefer students to learn "ahistorical" techniques or methodologies.

and syntaxes. In contrast, the partial legitimation of the notion of avant garde in the visual arts has been accompanied by an increased erosion of the boundaries between high and low or professional and amateur stylistic forms. Because of the resulting legitimation of subjectivity, the practice and the teaching of the visual arts have become distinctive activities entered in distinctive paradigms. Thus, there is a constant decline in the importance attached to the copying of canvasses or statues in painting and to throwing in ceramics, and this decline cannot but accentuate further the segmentation of existing paradigms.¹⁹

But disciplines also differ from one another in terms of the *form* of the connections they establish between their time orientations and their rank ordering of the tasks to be performed by individual practitioners. This explains the differential fate experienced by museums across fields. At one end of the continuum, museums of science and industry have been initially built after the model of museums of natural history, institutions that are almost as old as museums of art and have originally aimed at serving the needs of a professional and a high culture. Yet, the early legitimation of a future- and progress-oriented ideology in the sciences has rapidly condemned scientific museums to run behind the times and to collect scientific artifacts that are necessarily worthless because of their obsolescence. Correspondingly, these past-oriented scientific museums can only be instruments of diffusion and they serve, as such, the need of a low or an amateur scientific culture.

At the opposite end of the continuum, the shift of the cinema from a low to a high culture status requires the legitimation of the work undertaken by current directors through the legitimation of the movies made by their predecessors. Past-oriented cinémathèques reflect this shift and are currently used as a socializing mechanism for newcomers in the profession.

In the center of this continuum, the ambiguous status of art museums reflects the

conflicting views that cultural elites hold toward the relationships between the time orientations and the distinction opposing high to low or professional to amateur stylistic forms. Since the middle part of the twentieth century, museums are simultaneously praised and criticized for being the temples of a past-oriented high culture. More than one hundred years ago, the "socialist" art critic Delecluze complained that museums were nothing but the "hospitals if not the graveyards of art." Today in spite of its ahistorical here and now orientations, the Centre Beaubourg in Paris is criticized for being a center of cultural reanimation rather than animation (as quoted by Huser, 1978; Huxtable, 1978). In short, because the notion of avant garde is more problematic in the case of the arts than of the sciences, the functions of museums remain more uncertain in the first than the second context.

A Comparative Analysis of Artistic and Scientific Revolutions

The institutionalization of creative activities, and the resulting control that paradigms exert on practitioners and their ideas, both influence and are influenced by recurrent tensions between the needs for stable beliefs and the need to unmask old truths as illusions (Hudson, 1972; Peckham, 1969). In their normal forms, both the arts and the sciences consist of puzzle-solving activities within a preexisting framework. But because artistic and scientific disciplines *have* histories, as much as they *are* histories (Moscovici, 1968:48), they also experience revolutions. In science, "electricity has perhaps existed as an abstract force before becoming a source of energy; yet it had no historical meaning as long as men did not ask questions about it" (Gramsci, 1959: 172). Similarly in the arts, "there was no fog in London before Turner" (Wilde, as quoted by Renoir, 1962: 212). In short, all disciplines experience discontinuities.

The salience and the frequency of these discontinuities may differ across specific disciplines. In the physical sciences, the small size of research communities, their

¹⁹ This decline is accompanied by a rejection by students of teachers who are primarily concerned with the diffusion of their own styles (Strauss, 1970).

professional insulation and the limited scope of the activities to be performed by individuals slows down the occurrence of revolutions but commits the entire profession to subsequent shifts of values (Barnes, 1973:182-98). Correspondingly "the ratio between the trust and the rejection of existing hypotheses evolves within narrow limits that are closer to the trust side" (Campbell, 1974: 5; 1977). In contrast, the high permeability of artistic or of social science communities and their low patterns of division of labor facilitate the occurrence of revolutions whose effects are only partial and experienced by a limited segment of the population (Hudson, 1972).²⁰

Regardless of these overall contrasts, one might assume that the differential traits of artistic and scientific revolutions reflect the life cycles of the paradigms specific to each field. If this is so, one should compare the processes by which little art has evolved into big art and little science has become big science (De Solla Price, 1963). Given the fact that a paradigm requires a certain amount of time to achieve a visibility twice as large as at the time of its inception (as measured in terms of the number of its adherents, their works, the references they elicit), does the logistic growth of various paradigms follow patterns that are specific to each discipline? Are such patterns similarly influenced by floor and ceiling effects? Clearly, Seurat anticipated the research suggested here when he wrote to Signac, "The more we are to use the technique of dots, the less original it will be and the more artists will explore new frontiers or boundaries" (as quoted by Perruchot, 1966). Further, are such patterns independent of historical time, or is the logistic growth of paradigms faster in the case of newer than older disciplines or faster as one gets closer to the twentieth century?²¹

²⁰ It would be necessary in this regard to compare those fields where the emergence of new paradigms results primarily from the immigration of practitioners already established in other disciplines with those fields where this emergence reflects primarily the work of newcomers to the profession.

²¹ For example, one could compare the logistic growth of Impressionism in painting and of atonalism in music. Yet it would remain necessary to ascertain whether the contrasts eventually observed in this

In the same way, it remains necessary to identify similarities and contrasts in the outcome of artistic and scientific revolutions. In both cases developmental processes seem to be marked by an accentuated articulation and specialization and hence by a transformation of the boundaries separating disciplines from one another (Kuhn, 1970: 172). But does the succession of these stages reflect a closed evolutionary scheme in which exemplars can be viewed as increasingly more accurate approximations of a permanent Truth or Beauty? Or is the evolution of artistic and scientific exemplars a patchwork of random mutations (Kuhn, 1970:173; Gablik, 1976:10; Campbell, 1977)? Assumptions made in this regard may have differing histories in the case of the arts and the sciences. Patterns of ideological commitments have followed diverging routes between the two fields.²²

Summary and Conclusions

Our general purpose in this paper has been to assess the extent and the determinants of the variability underlying the organizational patterns of specific paradigms both *between* and *within* the arts and the sciences. On the one hand, all disciplines confront similar problems in their attempts to rationalize the control of the two major forms of scarcity with which they are confronted, that is access to raw materials and access to the public. On the other hand, division of labor also fosters a growing segmentation of artistic and scientific disciplines and their respective audiences. Because of the differential responses of culture producing disciplines to technological innovations or to changes in economic forces, their communities

regard reflect the differential technical characteristics of the two fields or historical changes in the use that distinctive art worlds make of new means of diffusion.

²² It is interesting in this regard to note that Gablik's stance toward the evolution of the arts comes at a time when most scientists take an opposite view as far as science is concerned. Whereas Gablik asserts that art evolves closer toward an *Esthetic Absolute*, the latter posit that the definition of science is culturally relative. Of course, such divergences are likely to increase with the accentuated segregation of the relevant occupations (Grana, 1964; Kuhn, 1970).

have increasingly distinctive structures. For this reason, there are also historical and functional variations in the processes by which practitioners within each discipline, negotiate the definition of (a) the tasks to be performed, (b) the rewards to be allocated, (c) the socialization of newcomers in the profession and (d) the distinction between normal and revolutionary practices.

An analysis of these negotiations highlights the major requirements of a sociology of creativity. The first of these requirements is to evaluate the variability of the modes of interaction between the members of a specific discipline and the outcome of their activities. Thus, it does not make sense to speculate whether "works of art or works of science illuminate one another" (Meyer, 1974:163-210). Nor does it make sense to state that we do not read Shakespeare in the same way that we read Newton as long as we do not ascertain whether the "we" refers to artists, scientists, or to specific segments of their respective audiences.

Secondly, the relationships that develop between works of art or works of science are not independent of the interactions among practitioners or between them and their respective publics. The production of an artwork or of a scientific theory may require a network of cooperative relations among various individuals, but their publications entail a succession of competitive behaviors among practitioners, between them and critics and between the worlds of "professionals" and the public at large. Thus a sociology of creativity should not be reduced to an examination of the *dyadic* relations between artists or scientists and their works, or between the members of a same creative community. Insofar as cultural worlds involve competing ideas and competing individuals, triads are more significant units of analysis than dyads.

Last, the negotiation of artistic or scientific evidence never takes place in a temporal vacuum. The time within which this negotiation takes place is threefold. First, the actors involved in the negotiation always use time as a benchmark against which they evaluate the product subjected to their scrutiny. At one single point in

time, *better* may mean *older* in certain disciplines but *newer* in others. Secondly, these negotiations involve a cycle of "give and take" until there is enough social stability in the patterns of exchange among practitioners or between them and their audiences to facilitate the formation of a partial or total paradigm. Third, negotiations are also part of a larger plot (Sennett, 1977:35). Insofar as a discipline experiences revolutions, it is as much subjected to the forces of disorder as to those of equilibrium. The transformation of paradigms is therefore as important to study both independently of and in relation to historical time as their perpetuation.

To conclude, our purpose has been to conjure the three demons confronting sociologists in their tasks. Sociological generalizations tend to be more ideological than scientific when they mask the internal variability of the phenomena analysed, and hence when they assume the existence of undifferentiated artistic or scientific paradigms instead of testing first the internal variability of artistic disciplines on the one hand and of their scientific counterparts on the other. In addition, these generalizations are also more ideological than scientific when they isolate esthetic phenomena from their surroundings and induce an arbitrary analysis of "attributes" rather than of relations (Payne, 1976). Indeed, such generalizations cannot but recreate the very stereotypes that their authors were supposedly interested in dispelling.²³ Last, these generalizations are more ideological than scientific when they remain ahistorical and are not focused on the divergences and convergences in the histories of specific disciplines. It is perhaps because such demons prowl continuously in the field of sociology, that this particular form of knowledge and its paradigms are sometimes described as an art form rather than as a science (Gouldner, 1976; Nisbet, 1976).

²³ At best, many sociologists of the arts use time independently of history. Their work offers in this regard a striking contrast with their counterparts in the sociology of science whose contributions are taking into account the interaction between sociological and historical times (Levi-Strauss, 1958).

GAPS AND GLISSANDOS: INEQUALITY, ECONOMIC DEVELOPMENT, AND SOCIAL MOBILITY IN 24 COUNTRIES*

ANDREA TYREE

State University of New York at Stony Brook

MOSHE SEMYONOV

University of Nebraska, Lincoln

ROBERT W. HODGE

State University of New York at Stony Brook

American Sociological Review 1979, Vol. 44 (June):410-424

Intergenerational mobility has been seen as influenced by both level of economic development and political democracy. Here, with a sample of 24 countries, the first of these relationships is assessed. The observed effect of economic development (GNP/capita) on mobility we conclude to be a spurious consequence of the shape of the stratification system, indicated here by the shape of both reward distributions and occupational distributions. Some discussion precedes this analysis about how the shape of a stratification system should affect mobility. Some discussion follows about how the shape of the system must affect political democracy, and leads us to a partial reinterpretation of the findings of Robinson and Quinlan (1977) on this topic.

BACKGROUND

Social mobility has long been viewed as an integrative mechanism for societies. Exogamous marriage rules (which assure mobility for women) are taken as responses to a need to link potentially conflicting groups through kinship. Toqueville saw opportunities for social mobility in the United States of the nineteenth century as contributing to the stability of political democracy in the country. He also saw the greater openness of the British than the French aristocracy as crucial in understanding the relative political stability of the two countries. A similar position has been more recently stated by Baltzell (1958), who argued that those societies in which ruling groups accept achievement elites into aristocratic membership will suffer less social turmoil than those whose aristocracies do not.

Social mobility has also been taken as the disintegrative consequence of the rationalization of production accompanying industrialization. The gap between social origins and social destinations was taken as an indicator of status inconsistency by any student of the problem who had both variables available, and justifiably so. Students of both the family and immigrant

ethnic minorities detailed the disruptive consequences of the mobility of offspring and their intermarriage with members of outgroups. Changes over time in the structure of opportunities and the conditions under which specific opportunities are available, effectively force social mobility, both upward and downward, as well as laterally between situations. Altered opportunity structures have consequences both for individuals and for societies. What may be integrative for society may be disintegrative for individuals, families, and social networks.

What the two perspectives have in common is a sense that a thorough understanding of a social structure at any time, *t*, is inadequate for an understanding of the behavior or satisfaction of its members. Both individual senses of satisfaction and the integration of the system is a function of actual movement that has occurred between *t* minus something and *t*, as well as movement anticipated between *t* and *t* plus something. Mobility itself has consequences.

This is a difficult position to argue in the current climate of our discipline. Blau and Duncan (1967) persuasively recast the interest in social mobility initiated theoretically by Sorokin in 1927 and, practically, by Rogoff in 1951 into a problem of status attainment in which no mobility variable has reason to appear. They argued that

* Address all communications to: Andrea Tyree; Department of Sociology; State University of New York; Stony Brook, NY 11794.

mobility correlations are unnecessarily inaccessible combinations of simple associations with origin and destination variables. The process by which mobility occurs could be more easily understood (more easily presented) without these troublesome mobility variables. They were both astute judges of their audience and truthful: If the variance of origin and destination variables is approximately the same (which it usually is) associations involving mobility and attainment are simple transforms of one another. Equations predicting attainment are easier to write sentences about than are those predicting mobility. To choose the path of easier presentation was surely productive: a bibliography of work on status attainment flowing from the original Blau-Duncan volume would fill half of this journal.

Blau and Duncan (1967) made a wise decision for students of the determinants and consequences of the social mobility of individuals. Their decision was an unfortunate one for the study of the determinants and consequences of social mobility for social systems. By focusing on describing the way occupational roles and statuses are allocated within societies, they drew attention away from differential levels of mobility as characteristics of social systems.

We do not wish to convey the impression that cross-national comparisons of social mobility are rare. Quite the contrary. The active support of the International Sociological Association at the beginning of the 1950s (ISA, 1951) promoted mobility studies in a number of European countries. This activity culminated in a comparative report of the cross-national findings by Miller in an entire issue of *Current Sociology* (Miller, 1960). Several others have ventured reanalyses of the original data, as well as adding to them data from the expanding body of occupational mobility studies around the world (Lipset and Bendix, 1959; Fox and Miller, 1965; Blau and Duncan, 1967; Cutright, 1968; Hazelrigg, 1974; Hazelrigg and Garnier, 1976). Recently, almost every study of intergenerational social mobility devotes a chapter or section to the comparison of the nation in question with some other countries. For example Broom and

Jones (1969) compare Australia to the U.S. and Italy; Garnier and Hazelrigg (1974) compare France to the U.S. and Australia; Kahl (1968) and Simmons (1975) compare mobility in different Latin American cities each in a different country; Mellic (1965) and Andorka (1971) try to compare experiences within communist Yugoslavia and Hungary with those in noncommunist countries; Tominga (1970) compares Bangkok to industrialized countries.

Two alternative, though not necessarily contradictory, explanations for variations in levels of social mobility run through these works. The first sees mobility as a function of political democracy, the second sees it as a function of industrialization. Sorokin (1927:160) argued the first, concluding: "Though the so-called democratic societies are often more mobile than the autocratic ones, nevertheless the rule is not general and has many exceptions." The view of American democracy as promoting uniquely high levels of mobility in the United States was accepted by Glass (1954) in his pioneering study of social mobility in Great Britain. Seeing high rates of social mobility as both preserving an existing system of social stratification and promoting the stability of democracy, Blau and Duncan (1967:439-440) acknowledged an association between democracy and mobility, but reversed the direction of causation to that implicit in Toqueville.

The alternative view of industrialization, rather than political democracy or egalitarian ideology, as determining the level of intergenerational occupational mobility, was first specifically taken by Lipset and Bendix (1959). They found little variation in rates of mobility in nine industrialized nations, and concluded that generic conditions of industrialization explained the uniformity of mobility. Despite a general consensus that relying on a variable constant in one's data as an explanation of findings is a poor research strategy, the view of Lipset and Bendix has prevailed.

The importance of industrialization was questioned relatively early in the history we are reporting. Fox and Miller (1965) compared patterns of upward and down-

ward mobility in twelve nations, relating the differences to G.N.P., education, political stability, urbanization, and achievement motivation. They concluded:

The level of economic development does not emerge as important with respect to upward mobility. . . . [E]conomic factors are important but they are not unique determinants of mobility nor do they operate in any simple way. (Fox and Miller, 1965:91)

Technical problems in the data analysis of Fox and Miller led their conclusions to be discounted (see Blau and Duncan, 1967:433). Industrialization quickly regained credibility as a determinant of intergenerational social mobility through Cutright's (1968) cross-national analysis of occupational inheritance (inheritance being what mobility is not).

How industrialization might influence mobility has received less attention than whether or not the two are related. The most thoughtful and detailed exploration of the mechanisms by which industrialization might promote mobility is Treiman's (1970). Yet even here, it is not clear what, about industrialization, loosens the ties of social origins and promotes mobility. Treiman can only suggest that increased industrialization implies expanded education, mass communication, urbanization, and geographical mobility. These in turn influence circulatory mobility.

The role of industrialization as a correlate of mobility recently came under attack by Hazelrigg and Garnier (1976). They rely on a sample of 17 countries that vary in level of economic development a good deal more than had those analyzed by previous students of the subject. Using energy consumption per capita as an index of industrialization and two variants of a measure of circulatory mobility (unfortunately unidentified in the 1976 paper) obtained after alternate Deming adjustments of the 17 mobility matrices, they conclude that "variation in the strictly endogenous process of labor mobility was *not* related to level of productivity" (Hazelrigg and Garnier, 1976:504).

The current position of this field is somewhat confused. The confusion is a consequence of two factors. First, the varying methodologies of the several contributors to the literature have led to vary-

ing findings. Second, other than the possible relationship with industrialization or political democracy, it is not clear why one would care to ask if one country has more mobility than another. The issue has not been cast by anyone as being important for understanding social organization.

The answer one gets to a question is dependent on the operational way the question is posed. Lipset and Bendix (1959) relied on outflow percentages in a trichotomous occupational structure (white-collar, blue-collar, farm). Miller (1960) continued with outflow percentages, but rephrased the question to focus on mobility into the top of social orders. Fox and Miller (1965) used a crude measure of upward mobility; manual to non-manual outflow percentages. Blau and Duncan (1967) attempted to eliminate the effects of shifts in marginals by switching to mobility ratios yet continuing Miller's interest in national differences in short and long distance mobility. Cutright (1968) moved away from the previous concentration on upward mobility by summarizing the mobility revealed in four-fold tables with a series of Yule's Q's. Hazelrigg, who started in 1974 with outflow percentages, moved by his 1976 article with Garnier to Deming adjustments of marginals and a summary measure of the circulatory mobility within the adjusted tables.

In addition to a changing methodology, this literature has had a changing data base. Lipset and Bendix, together with Miller, used samples from 12 western European countries and countries of European settlement plus a sample of Russian emigrés to the United States. Blau and Duncan (1967) reduced the sample to 11 countries. By 1976 Hazelrigg and Garnier could feel fairly confident of expanding this data base to number 17 countries, considerably more variable both economically and culturally than the early samples had been.

Mobility As a Characteristic of a Social System

The explanations offered for cross-national differences in mobility, when such differences have been found, have invariably referred either to the level of

productive capacity or the political organization of nations. Either industrialization is seen to require the allocation of individuals to roles on criteria at least partially inconsistent with ascription, or political democracy has been seen as requiring widely perceived mobility opportunities for its maintenance. Circulatory mobility has not been taken to be influenced by characteristics of systems of social stratification themselves. We do not understand why this has been so.

There has been considerable recognition that short-distance mobility is more common than long-distance mobility. It would follow that in societies in which opportunities for short-distance mobility are limited, the total amount of circulatory mobility also would be limited.

We can think of societies in which social position is defined reasonably clearly along class lines, with two or three discrete classes having fairly uniform economic rewards available within each, but having substantial economic differences between them. The vertically mobile in these nations must leap large socioeconomic gaps in the structure. We can think of other societies where social gradations from the top to the bottom are numerous and small, each one being nearly indistinguishable, yet, when taken together, covering a substantial distance. The stratification system of such societies is a sort of social glissando. Vertical mobility can occur on a wide scale in small steps. Even when long distance upward mobility is attempted, possible outcomes are not limited to success or stagnation; the existing intermediate statuses provide alternative compromise destinations.

Circulatory mobility can be viewed as a zero-sum game. Net of movement forced by changes in the occupational structure over time and differential fertility, one's move up implies another's move down. The prospective cost of circulatory movement to the well born is notably greater in a two-class society than in a social glissando: to fall is to plummet. In such societies the upper class has serious reasons to protect lucrative positions from invasion from below. The power that can be bought with affluence and prestige is likely to be used to this end. In the social

glissando there is less motive for high status groups to attempt to block the upward movement of others, for the cost of downward moves of their own offspring is less. The ability to block others is probably also reduced. A glissando of affluence and status does not promote discontinuities in power.

For both of these reasons we expect the shape of a stratification system to influence the level of mobility occurring within that system. Since the shape of stratification systems, or degree of income inequality, will be seen to be associated with the level of productive capacity (GNP per capita), we shall have to consider the independent effects of both variables on mobility.

DATA AND PROCEDURES

Our data sources differ little from other recent studies of comparative mobility. There is a limited body of mobility studies from which any of us can assemble our samples. The choice of which are acceptable for analysis is partly dependent on the way the problem is phrased and partly dependent on a subjective sense of what is and what is not acceptably reliable. We are able to expand the list of 17 countries used by Hazelrigg and Garnier to 24, largely by restricting our analysis to mobility between white-collar and blue-collar segments of occupational structures. Thus urban samples are more acceptable to us than they were to them. We also have access to national studies of occupational mobility in Israel and Canada that were not available when Hazelrigg and Garnier did their work. We have chosen to be more restrictive than they by limiting ourselves to samples of males. We do not feel confident enough of a congruence within nations of the mobility experiences of men and women to mix single- and two-sex samples.¹

¹ Cell frequencies for West Germany were retrieved from Kleining's (1971) article by a roundabout procedure. Kleining presents only outflow percentages and column totals, but no row totals. Following an observation by Tyree (1973: 579), we used the outflow distributions to compute mobility ratios within Kleining's table, inverted this matrix, and summed the elements of the inverted matrix

* Sample size after elimination of farm respondents where applicable.

** Only weighted sample size available. Total sample (all ages, both sexes) = 22,782.

The 24 countries in Table 1 vary considerably in type of government, level of economic development, and geographical location. As we shall see later, they also vary in income inequality. Data from the

across columns to obtain the row totals. There are other carefully executed mobility studies available that we have not included in our analysis, several dating from the 1950s. The reason for rejecting them here vary from case to case, largely being our own uncertainty of sampling procedures or dissatisfaction with the choice of population sampled. Most are from either European or South American cities. Since both of these areas are reasonably represented in Table 1, we do not feel the omissions to be serious. We do regret that we did not feel we could include Singh's (1972) data from Petaling Jaya, Malaysia or Tominga's (1970) from Bangkok. Petaling Jaya is a development town, inhabited almost exclusively by in-migrants. These migrants have experienced considerable spatial and occupational mobility; Singh acknowledges that their experience is not typical of Malaysians. Furthermore, in both samples the majority of fathers were farmers, reducing the sample size available for this analysis severely. In an analysis of farm-nonfarm intergenerational mobility both samples might be included profitably.

various surveys were collected idiosyncratically with investigators in each country resorting to occupational categories of use to them in their own work, but not necessarily of use to one wanting to compare the assembled data sets. This is a familiar problem to students of comparative stratification and mobility. The more detail one retains in a particular table, the less comparable it becomes to other tables. To the end of maximizing comparability, we have reduced the intergenerational mobility data from all countries to a series of four-fold tables: the white-collar/blue-collar status of respondents by the white-collar/blue-collar status of their fathers.

The highly aggregated nature of these resulting matrices eliminates potential problems arising from the small size of some of the samples. Use of 2 by 2 matrices also enables us, in a loglinear context, to obtain a unique estimate of mobility for each country—a possibility not so

readily available with more detailed origin and destination distributions.

Collapsing the original data to comparable blue-collar/white-collar categories on both the origin and destination variables, produces a three dimensional data matrix: 2 by 2 by 24. What we want of this matrix is a vector of estimates of the relative (to the other countries) odds in favor or against intergenerational mobility. Once we have it we shall be able to ask: To what is it related? To do this we must eliminate some known structural determinants of mobility as well as variability in sample size. The frequencies in each of the cells are functions of the size of each sample, the representation across the entire groups of countries of white- and blue-collar respondents, and the representation among their fathers of white- and blue-collar workers. A certain amount of mobility is forced by shifts in occupational distributions over time. This is partially represented by differences in the occupational distributions of father and respondents—all sons.

In addition, cell frequencies are functions of pairwise interactions of fathers' distributions and respondents' distributions, fathers and countries, and respondents and countries. To this point we have seven predictors of the cell frequencies: a grand mean (G); the marginal distribution of fathers (T_i^A), where $i = 1$ for white collar and 2 for blue collar; the marginal distribution of respondents (T_j^B); the 24 countries themselves (T_k^C); the interaction between the occupation of fathers and that of their sons (T_{ij}^{AB}); the interaction between the occupations of respondents and the countries in which they live (T_{jk}^{BC}); and countries in which their sons, the respondents, live (T_{ik}^{AC}).

These effects together predict a matrix of intergenerational mobility which would occur if the mobility processes of all the 24 countries worked the same way. Of course they do not all work the same way; some countries have more mobility than others. We can introduce the three-way interaction between father-respondent-country (T_{ijk}^{ABC}) to represent this greater or lesser experience of occupational mobility. At this point the model is saturated: The frequencies (F_{ijk}) in each of the 96

cells are exactly predicted. The model becomes:

$$F_{ijk} = G T_i^A T_j^B T_k^C T_{ij}^{AB} T_{jk}^{BC} T_{ik}^{AC} T_{ijk}^{ABC} \quad (1)$$

This is a multiplicative model. Expressed in the form of natural logarithms, it becomes additive. Our interest is with the estimates of T_{ijk}^{ABC} , the interaction term representing a particular country's relative propensity to occupational mobility. This term is a linear function of the logged odds ratios for each of the tables, the correlation between the two being 1.0.

The results of this exercise are presented in the first column of Table 2. The countries have been reordered from the alphabetical one in which they were presented in Table 1 to one based on their ranking by T_{ijk}^{ABC} , their relative mobility. Negative values mean greater mobility; positive ones, greater occupational inheritance. It is clear in this first column that nations do differ in the amount of intergenerational occupational mobility occurring in their populations. The most mobile populations are those of Israel, Canada, Australia and the United States. The least are those of Italy, the Philippines, Brazil, and Columbia.

Mobility and Economic Development

Lipset and Bendix, Cutright, Davis, and other past proponents of economic development, as either promoting occupational mobility or requiring it as a precondition, are supported by the mobility rates (lambda coefficients) in Table 2. These values are associated with GNP per capita in 1965 in the second column of Table 2. The correlation between these two variables is $-.601$. A certain interpretative distortion is created by relating observations about productive capacity at one time (1965) to findings about mobility processes at various times. The choice of 1965 GNP per capita does provide a simple way to measure productive capacity in constant dollars. The error entailed by not converting measures from varying dates to 1965 dollars cannot be great. GNP per capita is a fairly stable characteristic of nations across the limited period over

Table 2. Occupational Mobility Effects, Gross National Product Per Capita, Percent of Income Going to the Top Five Percent of Households, and the Percent of the Labor Force in Salaried Professional, Technical, Clerical, and Sales Occupations: 24 Countries

Country	Mobility Index	GNP/ Capita	% Income to Top 5%	% Salaried Prof., Technical, Clerical, and Sales

Colombia	.356	282	39.4*	9.7

* The World Bank (Jain, 1974) does not provide household income distributions for these countries. The values for the Netherlands, Denmark, Sweden, Norway, West Germany, and Colombia were estimated from the regression of household measures on measures reported by the Bank for income recipients for all countries in the source with both variables available. The values for Hungary and Poland were estimated from the regression of household measures on those computed over workers in the same way. The Bank provides no data at all on the income distributions of Belgium and Italy.

** Total professional, technical and related workers plus total clerical and sales, as salaried population is not available.

which these mobility data were collected. The correlation between GNP per capita in 1957 and 1965 for the nations in this sample is a substantial .956 (sources: Russett, 1964; Taylor and Hudson, 1972).

The variance in GNP per capita is quite large ($X = \$1,373.50$, $s = \$864.02$), which is largely a consequence of the outlying positions (in 1965) of the United States on the upper end and the Philippines, Brazil, and Colombia on the lower. A logarithmic transformation of these values is associated quite as strongly with the mobility tau coefficients in Table 2 ($-.668$) as are the GNP values in their raw form. Where societies are successful at production, ascription loses force in the allocation of individuals to roles.

We cannot determine here a direction of causation, if there be any. Indeed, the autocorrelation of GNP per capita over time

is so high and the number of years between measured occupational origins and destinations so variable (even within any one sample) as to render the task of establishing direction intractable to us. It may be that economic development requires not only a base of natural resources and investment capital (the first generated either through the land itself or through the training of its inhabitants; the second either by individual investors, governments, or international capital transfers), but also a population conditioned to social mobility, a situation creating Reissman's inner- and other-directed men and women. Social mobility may be a precondition for development (see Davis, 1962).

Instead it may be that economic development creates conditions by which the bonds of social origins are relaxed; opportunities emerge for which no existing so-

cial group is uniquely prepared or toward which none is uniquely oriented. We have no way of choosing between these two possibilities.

It is probably more than accidental that the four most mobile societies in Table 2 (Israel, Canada, Australia and the U.S.) either are or have been in the remembered past home to unusually high proportions of immigrants. All four take some pride in their immigrant history. In the most occupationally mobile population, Israel, more than 60% of the labor force is foreign-born. Most of these immigrants were educated and got their first jobs in other countries.² High rates of immigration imply rapid population growth and, probably, more extensive social change than elsewhere.

The percent of a population native-born provides an inverse indicator of immigration. It is available in various *U.N. Demographic Yearbooks* (1964; 1971; 1973) for 20 of these populations (all but Belgium, Colombia, Italy and Japan). This measure is quite strongly related to the mobility coefficients ($r = .757$). With the extreme case of Israel dropped, over the remaining 19 countries, this remains a substantial $r = .693$.

The omission of Israel from the estimation of the association between GNP per capita and mobility raises that estimate to .700 and the association between log GNP per capita and mobility to .728.

These data provide support for the view of social mobility as related to economic productivity. In addition, the relative size of immigrant populations seems a potent correlate of social mobility. We shall return later to a consideration of the relationships among immigration, productive capacity, and social mobility. Next, however, we should like to direct ourselves to the importance of the shape of stratification systems for mobility.

² An alternative to these GNP values as an indicator of productive capacity is Gross Domestic Product per capita which is available in the *World Tables* (World Bank 1976) in constant 1967-69 dollars for all years since 1960. We were able to compute GDP per capita for the closest possible year to the survey date for 21 of the 24 populations. No appropriate data are available for Hungary, Poland, or Puerto Rico. With this reduced sample, mobility is correlated .664 with GDP per capita and .701 with its logarithm.

Inequality and Mobility

The third column of Table 2 presents the percent of income going to the top 5% of households in 22 of the 24 countries. These values are taken as close to the date of the mobility samples as possible from data supplied by the World Bank (Jain, 1974).³ No data on the income distributions of Belgium or Italy are available in this report. What these income differentials—or what wealth differentials—indicate is stratification; how much space is between those on the top and those on the bottom of a stratification system. The larger the percent of income going to the top 5% of households, the less is left to be divided among everyone else. Considerable care should be exercised in interpreting these numbers. The indexes for countries that have a large proportion of small families—typically wealthy, developed countries—are raised by this demographic fact. Kuznets (1976:87) expresses this effect clearly:

The smaller family or household usually receives a smaller income than the larger units, so that the family or household income for a one- or two-person unit is well below the countrywide mean. The proportion of such smaller units among all families or households is far greater in the developed than in the less developed countries—which contributes a much greater inequality component in the size distribution of family or household income in the developed than in the less developed countries.

Thus, for indicating how equally or unequally income is distributed to individual people, indexes for developed countries overstate inequality, while those for less developed countries understate it. Nevertheless, indicators of the size distribution of income provide a place to start thinking about the role of stratification in the process of development and in social mobility.

The correlation between the lambda coefficients in column 1 and the indexes of income inequality is .764. Where income

³ This working paper has since been published by the World Bank (Jain, 1975) with the same title and authorship as the working paper cited here. There are slight discrepancies in the two sources.

is more equally distributed, circulatory mobility is also greater. Where income differentials are greater, social origins are most powerful in determining social destinations.

Inequality is also related to productive capacity, with GNP per capita and income inequality being related by an $r = -.539$. We can entertain the hypothesis that both of these variables independently influence the rate of circulatory mobility. Here economic development creates a demand for an increasingly rationalized allocation of individuals to occupational roles, and relative equality of rewards creates the social conditions which reduce personal and family disruptions consequent to social mobility.

Unfortunately, the data do not provide strong support for this dual argument. In standard form (values in parentheses are standard errors),

$$\begin{aligned} \text{Mobility} &= -.288 \text{ GNP} \\ & (.163) \\ & + .609 \text{ Inequality}, \text{ with } R = .802. \\ & (.163) \end{aligned}$$

With GNP per capita transformed to its logarithm, this becomes,

$$\begin{aligned} \text{Mobility} &= -.301 \log \text{GNP} \\ & (.180) \\ & + .571 \text{ Inequality}, \text{ with } R = .798. \\ & (.180) \end{aligned}$$

In both of these equations the effect of productive capacity is about one and one-half times its own standard error, while the effect of inequality is both significant and substantively impressive.⁴

⁴ Using the GDP per capita measure reported in fn. 2 as an alternative indicator of productive capacity, we lose five cases; the three missing GDP/capita and the two missing income data. We gain temporal proximity of the measurement of productive capacity and mobility. The effect of inequality is still more substantial.

$$\begin{aligned} \text{Mobility} &= -.360 \text{ GDP} \\ & (.173) \\ & + .562 \text{ Inequality}, R = .821; \text{ and} \\ & (.173) \end{aligned}$$

$$\begin{aligned} \text{Mobility} &= -.372 \log \text{GNP} \\ & (.188) \\ & + .526 \text{ Inequality}, R = .816. \\ & (.188) \end{aligned}$$

What has previously appeared to be an association between mobility and industrialization or productive capacity appears to be a spurious consequence of the association of relative economic equality with both.⁵

Reward Structures and Occupational Structures

We have allowed a certain confusion between occupational structures and reward distributions. We have argued that circulatory occupational mobility is a function of the shape of occupational distributions. The availability of many middle-status jobs renders upward mobility easier. We then argue that mobility is a function of the shape of reward distributions; that the existence of an abundance of positions yielding a continuum of incomes renders potential downward movement less threatening and attempted upward movement more promising of at least some success. We have provided a test of the second argument by relating an index of the shape of income distributions to circulatory mobility.⁶ We have not provided any direct test of the first: we have only assumed that a glissando of positions and a glissando of rewards go together. We are better able to measure

⁵ One of the reviewers of this manuscript suggested our findings might be biased by our inclusion of one-city samples for the measurement of mobility. All four of the Latin countries are represented by only one city, while measures of their productive capacity and income distribution refer to the whole country, with these countries omitted, in standard form,

$$\begin{aligned} \text{Mobility} &= -.395 \text{ GNP} \\ & (.190) \\ & + .489 \text{ Inequality}, R = .698; \\ & (.190) \end{aligned}$$

$$\begin{aligned} \text{Mobility} &= -.367 \log \text{GNP} \\ & (.202) \\ & + .459 \text{ Inequality}, R = .678. \\ & (.202) \end{aligned}$$

⁶ All calculations reported in this article that include income to the top 5% of households were first run using both Gini coefficients and their logarithms. The findings are much the same, sometimes making our case weaker, sometimes making it stronger. Being unable to present all the various (interdependent) tests in one paper, we have chosen the presentation we feel to be more concise and more readily accessible.

the shape of reward distributions than the shape of occupational distributions. While we are not completely without resources for comparing occupational distributions, they are less than ideal.

Braverman (1974) argues that the working class includes, in addition to its usual incumbents, salaried professionals, technicians, clerical and sales workers. These are the middle status occupations that have proliferated to fill the center of the occupational structure in modern developed nations. The *Yearbook of Labor Statistics* (International Labor Office, 1973-1976) has included since 1963 data on major occupational distributions and class of worker. We have combined salaried professional, technical and related workers with salaried clerical and retail sales as a reasonably direct indicator of the size of the kinds of middle-level positions that can link the top to the bottom on an occupational hierarchy. These are expressed as a percent of the total labor force in column 4 of Table 2. Each calculation was made for a year as close to that of the relevant mobility survey as possible. Puerto Rico has been omitted as no appropriate data exist before 1976, which is two decades after the mobility survey.

What we ask of these data is whether the shape of occupational distributions can explain the relationship between industrialization and mobility as the shape of reward distributions has. The answer is an unequivocal, yes. Let us call the occupational variable in column 4, Midocc, in recognition of its intended capturing of the socially bridging middle status occupations. Then

$$\begin{aligned} \text{Mobility} = & -.067 \text{ GNP} \\ & (.251) \\ & -.686 \text{ Midocc} \quad , R = .740, \\ & (.251) \end{aligned}$$

$$\begin{aligned} \text{and Mobility} = & -.169 \log \text{GNP} \\ & (.270) \\ & -.598 \text{ Midocc} \quad , R = .745. \\ & (.270) \end{aligned}$$

Again the numbers under the regression coefficients are their standard errors. Even more decisively than before the evidence points to a social glissando, created

by occupational positions linking an elite at the top of a social order and the rest of the structure, as determining circulatory mobility. The originally observed relationship of mobility and industrialization must be concluded to be spurious.

An Alternative Class Line

Our argument has been largely a theoretical one. The evidence in its support is limited to circulatory mobility across a supposed white-collar/blue-collar line. We have established that this line is weaker where reward and occupational distributions are relatively continuous than where they are discontinuous.

There is reason to suspect a white-collar/blue-collar distinction as the crucial basis of class definition in most societies. We argue that social glissandos are inconsistent with the intergenerational transmission of class. We must be willing to draw hypothetical class lines anywhere in the social hierarchy. We should like to be able to measure circulatory mobility between capitalists and everyone else, for this would be responsive to a conviction within the social sciences of a persistence, even in modern post-industrial societies, of class membership based on ownership and control of the means of production. The data available to us are not adequate to this task.

We can ask whether the shape of the social structure is more important than economic development in explaining mobility between farm and nonfarm sectors of labor forces. There are reasons more persuasive than habit to suggest this as a relatively impenetrable line in occupational structures (Blau and Duncan, 1967: chap. 2). Farmers and nonfarmers tend to be separated in space more than are white- and blue-collar workers.

We can estimate circulatory mobility across this line for a subsample of 13 of the populations in Table 1 the same way the estimates of white-collar/blue-collar mobility were made. Since men in agricultural destinations or from agricultural origins were eliminated from the previous analysis, this measure of mobility is logically independent of the one in Table 2.

The variable mobility now refers to the

3-way interaction term saturating the log-linear model of the 2 by 2 by 13 matrix of men of farm-nonfarm origins and destinations in 13 countries (or the logs of the odds ratios in each 2-dimensional matrix). Estimated for these 13 populations alone,

$$\text{Mobility} = .011 \text{ GNP} + .756 \text{ Inequality,} \\ (.224) \quad (.224)$$

$$\text{and Mobility} = -.123 \log \text{GNP} \\ (.227) \\ + .715 \text{ Inequality.} \\ (.227)$$

Inequality is again the percent of income going to the top 5% of households. It alone determines farm-nonfarm mobility in this sample. The effect of industrialization or productive capacity is far less than its standard error. Though the sample is regrettably small, it appears that what draws men off farms or onto them from nonfarm origins is not the affluence of their countries but the shape of the reward distributions within them.

Mobility and Immigration

Earlier in this paper we noted that the countries with the most mobility were countries with histories of unusual immigration. We reported a correlation of .757 between the mobility coefficients and the percent of populations native-born. We promised to return to consider the importance of immigration for social mobility.

This importance is well documented in the United States, where each new immigrant wave has pushed earlier arrivals up the social structure. Except in the Northeast, persons of native birth have never been preponderant among factory workers (Gutman, 1979). They have been pushed up by immigrants who took the factory jobs. Other societies which have been major recipients of immigrants seem to have functioned in much the same way.

Immigrants enhance measured mobility in recipient countries in two ways. First, separated from their communities of origin, the status of their parents is weakened as a predictor of their destinations. Second, typically entering nearer the bottom than the top of the social orders to which they move, immigrants push natives up by

increasing the size of the population and the productive capacity of the economy.

We all recognize that immigrants are attracted by countries of opportunity. It has not been clear what "opportunity" means to an immigrant—whether it is wealth (as GNP per capita) or the availability of a social ladder with many little rungs, a ladder one might reasonably expect to climb. The evidence in these 24 countries is not that immigrants are drawn to industrialization or high GNP per capita ($r = -.189$) so much as they are drawn to social glissandos. The correlation between percent native-born and the percent of income going to the top 5% of households is .354, its correlation with the Midocc variable is $-.591$.

Assessing the causal structure of these four variables—inequality, industrialization, immigration, and circulatory mobility—is beyond the scope of this paper.

DISCUSSION I: INTER- AND INTRAGENERATIONAL MOBILITY

The cross-national intergenerational mobility data assembled here have supported our expectations. On the theoretical grounds which directed us, we should have to expect inequality to be similarly related to *intragenerational* mobility. There is some reason to think that this prediction might not fare well if confronted with appropriate data.

We know that, across individuals in one society, intergenerational and career mobility are negatively related.⁷ Those who

⁷ Whether the correlation between inter- and intragenerational mobility is negative or positive in a particular society is dependent on the relative magnitude of three zero-order correlations. The mobility correlation can be estimated as follows. Where X = social origins, W = career beginnings, and Y = social destination,

$$r_{(Y-X)(Y-W)} = \frac{1 - r_{YW} - r_{YX} + r_{WX}}{\sqrt{2(1 - r_{YX})(1 - r_{YW})}}$$

This reduction of the mobility correlation assumes that the variances of the three status variables are equal. To the extent that they are not, this estimate will be in error. As a practical matter, the error is not great. It is clear from this simplification that only in a

move far from their social origins to their career destinations do not tend to be the same persons who move up from their career beginnings. For those assuming the higher status positions in modern society, most enter the occupational structure in high status positions after lengthy education, whatever their social origins. This does not necessarily mean, however, that indicators of levels of inter- and intragenerational mobility for societies need be expected to be negatively related.

There are other reasons that should lead us to expect the negative relationship. Goldthorpe (1966:654) reasoned "to the extent that education becomes a key determinant of occupational achievement . . . an increased rate of *intergenerational* mobility in advanced societies is likely to be associated with some limitation of *intragenerational* or 'career mobility.'" To Goldthorpe it is not that inter- and intragenerational mobility are incompatible, but that an increasing importance of education for role allocation leads the larger part of intergenerational mobility to be accomplished by the point of entry into the labor force. It is efficient for societies to adjust to changing occupational structures with a succession of differentially trained cohorts. It is not so efficient to retrain and promote existing labor, for the return on the training investment is less.

The intergenerational mobility we have addressed here is the sum of two steps; movement from origins to career beginnings and from career beginnings to social destinations. We have found the shape of the structure of rewards to be related to the total movement. We have not established how it is related to either of the two pieces in that movement. If a social glissando promotes mobility through its potential of many little steps; we should expect to find the mobility whether it be measured between parent and child or within an adult career. There are grounds to suspect that, had we appropriate data, we would not find the second.

society with a rather strong association between origins and career beginnings (r_{wx}) and relatively weak intragenerational (r_{vw}) and intergenerational (r_{vx}) associations, could the mobility correlation have a positive sign.

DISCUSSION II: POLITICAL DEMOCRACY

While we did not set off to study political democracy, our data analysis has drawn us to a literature on the relationship between economic inequality and political democracy. We have focused on the relationships among productive capacity (or economic development), inequality, and mobility. We have viewed mobility as a consequence of inequality and productive capacity. Most recent sociological work on cross-national differences in inequality have been uninterested in social mobility, but quite concerned with the effects of political democracy. The concern has been with understanding the structure of relationships (and the direction of causation) among political democracy, economic development, and inequality. By arguing that social mobility is an orderly function of two of these variables, we necessarily raise the question of how it might be related to the third, and how all four might be related to one another.

Lenski (1966) argued that political democracy reduces income inequality. Cutright (1968) addressed this hypothesis with data and was unable to reject it. Even after controlling for the level of economic development, he found political democracy and income inequality to be negatively related. Jackman (1974) did reject Lenski's hypothesis, finding net of economic development, no relationship between democracy and inequality. To Jackman economic development was the driving force; both democracy and equality were consequences.

Rubinson and Quinlan (1977) try to reconcile the differences between Cutright and Jackman. They devote much of this article to issues of scaling, which lead them to concur with Cutright and Lenski: Political democracy is related to personal income inequality even after economic development is controlled. They then attempt to reverse the direction of causation, arguing that democracy does not determine inequality, inequality determines democracy. In this argument they anticipate much of the reasoning that led us to view inequality as the potential determinant of social mobility in the early part of this paper. They see income inequality as

indicative of the class structure of a society and the class structure as determining the political order.

Thus, when we compare countries on inequality, basically we are comparing their class structures and, particularly, the degree to which they are dominated by a middle class. It is interpreting inequality as an indicator of class structure that leads to the hypothesis that social inequality affects democratization. (Rubinson and Quinlan, 1977:616)

We have argued that equality leads to mobility. Rubinson and Quinlan (1977) find relative economic equality leads to political democracy. We all conclude that the influence of economic development on either political democracy or social mobility is weaker than the influence of inequality.

To students of politics, the shape of the social structure has consequences for the way a society governs itself, the ways decisions are made. To us as students of social mobility, the shape of the social structure influences the degree to which ascription governs occupational role attainment. Both the way a society makes its decisions (democratically or otherwise) and the way it transmits roles from one generation to the next are determined by social structure. Social glissandos have both more political democracy and less continuity of status across generations.

There is a basic difference in the way Rubinson and Quinlan and we interpret what we find. To Rubinson and Quinlan the effect of inequality is taken as evidence of the importance of a relatively affluent and politically powerful middle class. They view social orders as structures of classes. We interpret the effect of inequality we find as evidence of the unimportance of class or, phrased differently, the importance of having a social structure so continuous that classes are not identifiable.

In one sense the difference in interpretation between us is unimportant; we are both asserting the shape of the social structure to be influential for social processes. In another sense the difference is important in that we see different things about the shape of the social structure as having these consequences.

Rubinson and Quinlan (1977) do not

provide any evidence that where economic inequality is low there exists a middle class which dominates the society politically (see their discussion on p. 616). Our findings do provide some evidence that where inequality is low it is unlikely that coherent classes exist, at least with identifications strong enough that they are reinforced by the kinship system, either intergenerationally, as between parents and children, or intragenerationally, as between siblings. Thus we are inclined to reinterpret the findings of Rubinson and Quinlan: Political democracy is not dependent on a strong middle class, but on weak classes.

In recent years the study of social mobility has progressed rapidly in sociology; the study of social stratification has not. We are not happy at having had to resort to an index of the size distribution of income to measure the shape of social hierarchies, just as both Cutright and Jackman regretted having to use sectoral income inequality as their measure. We do not think—and do not want to imply that we do—that income distributions define social stratification. We are aware that societies also differ in their distributions of wealth, political power, bureaucratic authority, and prestige. Any measure of income inequality (Gini coefficients, Kuznets indexes, income to the top 5%, the third quintile, etc.) can only provide a crude approximation of a social hierarchy. Though the measurement is not conceptually satisfactory, it has been of practical use in this research. The shape of a stratification system has consequences for the level of intergenerational circulatory mobility through the system.

CENTRAL CITY WHITE FLIGHT: RACIAL AND NONRACIAL CAUSES*

WILLIAM H. FREY

University of Wisconsin, Madison

American Sociological Review 1979, Vol. 44 (June):425-448

Although residential "white flight" from large central cities is hardly a new phenomenon, its cumulative adverse impact on the residual population has led policy makers to be wary of instituting programs which will further exacerbate the process. Recent policy debates have evolved over the question of whether white city-to-suburb movement is affected more significantly by racially-motivated causes, or by conditions associated with the general economic and ecological conditions in the city. The present study assesses a number of previously suggested factors related to race, central city decline, and demographic structure as determinants of the white city-to-suburb movement streams in 39 large SMSAs. Treating this stream as a product of two separate mobility stages, this analysis suggests that most factors, both racial and nonracial, affect central city flight less through the decision to move, than through the choice of destination. Fiscal and ecological features of the metropolitan area are demonstrated to be important in the explanation. However, racial effects cannot be dismissed.

INTRODUCTION

Neither the residential "flight" of whites from large central cities to their expansive suburbs nor the adverse consequences of this movement for remaining city residents are particularly new phenomena. Shortly after white suburbanization peaked in the 1950s, Grodzins (1958:1) in a perceptive essay noted:

Almost nothing is being done today to meet what is likely to be the nation's most pressing social problem tomorrow. The problem can be simply stated in all its bleakness: many central cities of the great metropolitan

areas of the United States are fast becoming lower class, largely Negro slums.

Since that time, evidence has tended to confirm that the cumulative redistribution of white residences and jobs out of the urban center has led to a lower quality of life for the minorities and poor left stranded in the core (Kain, 1968; National Advisory Commission on Civil Disorders, 1968) as well as to fiscal crises for many central city governments (Advisory Commission on Intergovernmental Relations, 1973). Although various public policy measures have effected modest gains in improving the living conditions of the urban poor (deLeeuw et al., 1976), one can hardly be complacent when 1977 figures show that 62% of the metropolitan poor live in central cities, and 45% of these live in low income neighborhoods (U.S. Bureau of the Census, 1978).

The fiscal crisis in city governments according to many experts has not yet reached its peak, particularly in older metropolitan areas (Pettengill and Uppal, 1974; Peterson, 1976). At present, the residents of financially strapped cities are faced with prospects of increased taxes, lower levels of service and, for those dependent on local government jobs, higher unemployment. Recent trends toward diminished federal contributions to the city's plight portend a bleak future. In light

I want to thank Karl E. Taeuber and Franklin D. Wilson of the Sociology Department, Katherine Bradbury of the Brookings Institution, Avery M. Guest of the University of Washington, and Christine H. Rossell of Boston University, for their suggestions and reactions to this paper at various stages of its development. I am also grateful to Karl and Alma Taeuber for making available school segregation indices for central city school districts and to Seymour Spilerman for making available his data on racial disturbances.

of this situation, it becomes apparent that central cities can ill afford to sustain further reductions in their nonpoor, non-minority populations.

It is small wonder then that various policy proposals aimed at lowering unemployment or achieving greater racial equality are carefully evaluated according to their potential impact on further white flight. The ghetto enrichment strategy spawned by the Kerner Commission report has been held up to such scrutiny (Kain and Persky, 1969; Harrison, 1974). More recently, the white flight implications of enforced school desegregation policies have become the focus of debate (Coleman et al., 1975; Farley, 1976a; Orfield, 1976; Pettigrew and Green, 1976a; 1976b; Coleman, 1976a).

In such debates, conventional wisdoms often get substituted for empirical evidence. One such conventional wisdom suggests that current white flight is still influenced by racial motivations (assuming that it had been during the 1950s) and that policies which would increase either the numbers or level of integration of blacks within the city will lead to a further loss of whites. An alternative explanation suggests that present flight to the suburbs is a consequence of the continued expansion of the metropolitan community which includes the dispersion of jobs and housing as well. Given the relatively static boundaries of the central city, past movements of nonpoor individuals toward greater housing and job opportunities in the suburbs have led to even further deterioration of the economic and environmental conditions within the city political unit (Bradford and Kelejian, 1973). Each explanation implies different flight consequences for proposed policies, leaving proponents and critics of a policy free to embrace the explanation which best supports their cause. Unfortunately for urban analysts, no empirical study using recent data has yet been undertaken which disentangles competing explanations of white city-to-suburb mobility. This is the purpose of the present investigation.

White Flight: Postwar and Present

A reasonable case can be made that the suburban flight of whites which occurred

immediately after World War II resulted in part from racial motivations. There is general agreement that the unprecedented levels of postwar suburbanization were mitigated by a unique set of economic and demographic circumstances which produced a heightened demand for housing, matched later by increased rates of suburban construction (Duncan, 1962; Glenn, 1973). However, available evidence also suggests that racially motivated movement patterns and discriminatory housing practices, when superimposed upon market forces of the period, served to exacerbate the selective mobility of whites to the suburbs. A facilitating factor in this regard was the substantial increase in black migration from the rural South to northern cities which took place in the 1940s (Hamilton, 1964). The large numbers of black in-migrants exerted even greater pressures on an already tight wartime housing market, and their relegation to exclusively black neighborhoods contributed to further piling-up in these areas.

After the war, the increased availability of suburban housing permitted an outward movement of central city whites as well as an expansion of blacks into previously white neighborhoods. Linkages between these two processes for cities which had undergone both black increases and white decreases in population are suggested in the Taeuber and Taeuber (1965a) study. Their data document a fairly systematic racial transition process wherein affected city neighborhoods experienced both black population increases and white decreases. Newly-invaded neighborhoods tended to be middle-class in character, and the black "invaders" were often higher in status than resident whites. An analysis of vacancy patterns and white resident characteristics suggests that the suburbanward movement of high status whites came disproportionately from invaded and partially black neighborhoods rather than all-white areas of the city.

Although these data do not indicate the existence of a widespread racially-induced flight consistent with common conceptions of neighborhood tipping or "blockbusting," a more subtle racial effect is suggested. The high level of mobility on the part of white city residents

could be attributed largely to a pent-up housing demand rather than a response to black in-migration. However, the overwhelming selection of all-white destination neighborhoods—located primarily in the suburbs—by these movers can be viewed as a discriminatory process. As the Kerner Commission put it:

“Massive transition” requires no panic or flight by the original white residents of a neighborhood into which Negroes begin moving. All it requires is the failure or refusal of other whites to fill the vacancies resulting from normal turnover. . . . (National Advisory Commission on Civil Disorders, 1968:245)

Since both market and nonmarket discriminatory practices effectively guaranteed to movers all-white neighborhoods in the suburbs, an undeterminable portion of white postwar suburbanization can be attributed to racial motivations on the part of individual movers and to more pervasive discriminatory housing policies on the part of both public and private agencies (Foley, 1973; Taeuber, 1975a).

Despite the continuing persistence of residential segregation and increases in the proportion of city blacks through the 1960s (Taeuber, 1975b; Schnore et al., 1976; Frey, 1978b), it is not likely that recent white out-movement from large central cities is as heavily influenced by interracial housing dynamics as had been the case in the 1950s. To begin with, the unique housing market situation which facilitated widespread racial transition during the postwar period has not been repeated in large central cities. Second, the nature of black migration has changed dramatically. Over the past two decades, black-recipient cities have come to experience lower levels of black net in-movement, greater diversity of origins among in-migrants, and higher status selectivity among in-migrants from all origins than in the 1940s and early 1950s (Taeuber and Taeuber, 1965b; Manpower Report of the President, 1974; Farley, 1976b). These trends tend to slow the pace of neighborhood transition and decrease the status disparity between black and white city residents. Third, there has been a change in white attitudes toward racial residential integration. According to re-

cent surveys, a majority of whites now endorse such integration at least in principle (Pettigrew, 1973; Hermalin and Farley, 1973). Finally, as a result of continuing suburbanization over the past three decades, a major portion of metropolitan whites already has been relocated into highly segregated suburban communities leaving behind those who either prefer a city residence or are unable to afford the move. Recent analyses have demonstrated that residential segregation at the metropolitan level exceeds that within the central city per se (Sørensen et al., 1975; Farley, 1976b; 1977).

It is conceivable that attempts to desegregate central city schools could provide a motivation for suburban flight similar to that generated by the neighborhood transition process. However, the overall impact of such movement is likely to be minimal if only because of the limited subpopulation affected (i.e., city whites with school-age children in public schools). Furthermore, available evidence suggests that school-induced flight, unlike the widespread residentially-induced flight of the 1950s, is not tied to community housing market mechanisms which influence population redistribution patterns (Farley, 1976c; Snyder and Kelly, 1977).

A strong argument can be made that *current* white flight is largely a response to deteriorating economic and environmental conditions within central cities. These deteriorating conditions reflect an increased isolation of the political central city from activities and resources in the larger metropolitan community—the cumulative result of population, housing, and employment expansion outside the city limits into a fragmented suburban political structure (Zimmer, 1975). In the process, the central city effectively has been stripped of the metropolitan area's high income population and a good deal of its industrial tax base. At the same time, it is still obliged to provide a host of nonresidential services which benefit workers, shoppers and visitors who reside in the suburbs, and to cater as well to the special needs of a large, poor and disadvantaged population within its own boundaries (Hirsch, 1971).

Suburban jurisdictions, in contrast, are

primarily dispensers of residential services (most notably, education), serve the needs of a more middle-class population, and can therefore impose less severe demands on their taxpayers, who are generally better off on an income per capita basis than city taxpayers. Intergovernmental transfers have served to moderate city-suburb disparities to some extent but far from completely (Advisory Commission on Intergovernmental Relations, 1973: Appendix B). Moreover, almost every attempt at city annexation or government reorganization within affected metropolitan areas has met strong opposition from suburban communities (Zimmer, 1976).

The implications of this city-suburb disparity for residential movement are plain. City residents of the most severely affected areas are being asked to pay higher taxes both on a per capita basis and as a share of total income than are their contemporaries in the suburbs. In return, they are not likely to receive proportionately better services and, in fact, can be virtually assured of lower quality schools and higher rates of crime than suburban residents (Peterson, 1976). It is likely, therefore, that the increased out-of-pocket costs and deteriorating environmental conditions associated with residence in financially plagued cities will provide additional impetus for suburbanward movement. Furthermore, city-suburb disparities have effected an aggregate relocation of employment opportunities out of the central core (Noll, 1970). In the 1960-70 period, decentralization has been particularly selective of blue-collar employment (Kasarda, 1976). Since proximity to workplace has been shown to bear some relation to residential location (Kain, 1965; Guest, 1976), the recent redistribution of employment opportunities well may induce further residential redistribution of blue-collar whites who have previously lived and worked in the central city.¹

¹ The expected increase in white city-to-suburb movement is a corollary of the so-called mismatch hypothesis. Put simply, this hypothesis suggests that the increasing suburbanization of blue-collar jobs and central city concentration of white-collar jobs

Hypotheses

This investigation will attempt to clarify the roles of factors that have been proposed to account for the current suburbanward movement of central city whites. In particular, we are interested in juxtaposing racially related flight effects with those that are associated with overall central city decline.

Findings in this study are based on a cross-sectional multivariate analysis of the white city-to-suburb movement stream for 39 large metropolitan areas as reported in the 1970 U.S. census. Although we are mindful of the fact that population change is the net of various mobility and migration streams in addition to natural increase (fertility-mortality), the focus on this single stream is consistent with policy makers' concerns over continued residential relocation of the existing central city population to other communities within the metropolitan area.² From an empirical standpoint, this stream represents a significant component of white population change in the largest

creates a mismatch between the skill levels of central city residents and available employment opportunities. A major consequence of this process is expected to be increased unemployment for city blacks who effectively are barred from relocating in a suburban residence. For blue-collar whites in the city, a suburbanward move becomes an expensive, but viable option. (See Harrison, 1974, for a discussion and critique of the mismatch hypothesis.)

² The movement streams which contribute to central city population change can be distinguished, analytically, between: (1) in- and out-migration streams which lead between the central city and points outside the metropolitan area; and (2) intrametropolitan suburb-to-city and city-to-suburb residential mobility streams (see Frey, 1978a). Although the former streams can contribute substantially to city population gains or losses, their magnitudes are generally influenced by metropolitan-wide employment and labor market factors. Of more concern to urban analysts and policy makers is the increasing deterioration of the central city viz its suburban communities with respect to social, economic, and other residential environment factors that serve to retain or attract movers from within the metropolitan area. Given that the size of the city-to-suburb residential movement stream is generally far greater than that of its counterstream in large declining cities (Taeuber and Taeuber, 1964; Tarver, 1969; Farley, 1976b), much attention has been given to isolating those factors which may promote a further out-movement of existing city residents.

central cities. Twenty-three of the 39 metropolitan areas in the analysis experienced central city white (nonblack) population losses over the 1960-70 period. Among these, the 1965-70 city-to-suburb stream (as can be determined from the 1970 census) accounted for, on the average, 77% of those losses. Moreover, among all 39 metropolitan areas, there exists a $-.82$ zero-order correlation between 1960-70 white central city population change and the size of the 1965-70 city-to-suburb stream (U.S. Bureau of the Census, 1973a; 1973b).

In proceeding with the analysis, we are guided by two underlying hypotheses. First, *we expect that current white flight can be accounted for largely by the deteriorating economy and social environment of the central city rather than by factors which are directly related to race.* Changes that have taken place since the immediate postwar years in the housing market, the nature of black migration, white attitudes toward racial integration, and the characteristics of central city residents, point to a diminishing racial effect on white suburbanward movement levels. The impetus for flight from today's central cities is more apt to be linked to deteriorating conditions in the central core which have accompanied the city's increased demographic and political isolation from the broader metropolitan unit. This position is supported by aggregate post-1960 statistics which indicate a continuing suburbanization of central city whites despite a sharp curtailment of black in-migration from 1950 levels (Long, 1975; Taeuber, 1972).

Our second hypothesis concerns the term *flight* as a characterization of the movement. Previous studies of residential mobility indicate that there are a variety of factors responsible for precipitating a local move, and further, that these factors tend to coincide with major life-cycle stages of the household (Rossi, 1955; Goodman, 1974; Speare et al., 1975). It is therefore reasonable to expect that selective white movement out of increasingly black central cities takes place as part of the destination selection process *after* the decision to move is made. This view of

white residential movement has been given support in the neighborhood racial transition literature, and it can hardly be characterized as flight. Hence, *we anticipate that racial influences on city-to-suburb movement, to the extent they exist, will operate primarily in the destination selection process.*

The test of the first hypothesis will permit a comparison of various race-related and non-race-related effects on white city-to-suburb movement levels, whereas the test of the second will give insights into how these effects are transmitted. A confirmation of the second hypothesis and not the first would imply that the implementation of racially sensitive policies will not evoke an immediate suburbanward flight but that the mobility consequences for such policies would be more gradual and long-term. A confirmation of both hypotheses should serve to moderate those arguments which suggest that racial influences significantly raise current levels of white city-to-suburb movement.

THE MODEL

To evaluate causes of white flight in terms of the hypotheses raised, we employ a general model of intraurban residential mobility which has been used elsewhere (Frey, 1978a; 1978b; 1978c; 1979). The model is based on the assumption that individual movement can be viewed as the outcome of two distinct stages: (1) the decision to move, and (2) the choice of destination. Although more elaborate conceptions of the residential mobility process have been advanced (Brown and Moore, 1970; Speare et al., 1975), this decomposition into two separate stages has proven to be an effective analytic device in a national study of moving behavior which found that different sets of explanatory factors can be related to each stage (Butler et al., 1969). Moreover, the two-stage analysis is superior to one which treats mobility *from* an origin *to* a destination as a single event since the former allows identification of causal factors at each stage and permits the researcher analytically to separate "pushes" from "pulls."

The aggregate-level counterpart to the individual two-stage mobility model suggests: first, that within a geographically delimited population (e.g., central city), a pool of movers will evolve over the course of a time interval; and second, that some proportion of these movers will select a destination outside the geographically delimited area (e.g., suburb destination). It is possible, therefore, for different community-level factors to be associated with the size of the mover pool—or the incidence of mobility among *residents* in the community—than are associated with the propensity of *movers* to select a destination outside the community. This distinction is important for testing our second hypothesis that racial factors will be less apt to motivate mobility per se than influence the selection of suburban destinations for central city whites.

Migration measures for both stages of the 1965–70 white (nonblack) city-to-suburb movement stream are estimated from 1970 census data for 39 SMSAs (Standard Metropolitan Statistical Areas) with single central cities and with populations greater than 500,000 (listed in Appendix C). This focus on the nation's largest metropolitan areas is predicated on aggregate trends, showing that it is the central cities of SMSAs in this size class which have experienced greatest levels of white population loss since 1960 (U.S. Bureau of the Census, 1971; 1978; Taeuber, 1972). It is also consistent with research on school enrollment declines which suggests that racially linked white flight is most apt to occur in the largest cities (Coleman et al., 1975). Seven metropolitan areas which would otherwise qualify for inclusion in this study (Honolulu, Hawaii, Jacksonville, Fla., Miami, Fla., Salt Lake City, Utah, San Antonio, Texas, San Diego, Calif., Washington, D.C.) had to be eliminated because a large share of the male labor force was in the armed forces, sufficient migration or independent variable information could not be obtained, or extensive boundary changes took place between 1965–70.

The two stages of the city-to-suburb movement stream are defined in terms of component rates:

Mobility Incidence Rate (MI) among city residents =

$$\frac{1965 \text{ city residents who moved within the city or to the suburbs of the same SMSA, 1965–70}}{1965 \text{ city residents who resided in the same SMSA, 1970}}; (1)$$

Suburban Propensity Rate (SP) among city movers =

$$\frac{1965 \text{ city residents who moved to the suburbs of the same SMSA, 1965–70}}{1965 \text{ city residents who moved within the city or to the suburbs of the same SMSA, 1965–70}}; (2)$$

The city-to-suburb stream mobility rate can therefore be defined as:³

City-to-Suburb Stream Mobility Rate (CS) among city residents =

$$\frac{1965 \text{ city residents who moved to the suburbs of the same SMSA, 1965–70}}{1965 \text{ city residents who resided in the same SMSA, 1970}}; (3)$$

Given the rates in (1), (2) and (3), the following relationships are evident:

$$CS = MI \times SP; (4)$$

$$\log CS = \log MI + \log SP. (5)$$

As shall be demonstrated below, the latter additive relationship is useful in attributing causal factors to city-to-suburb mobil-

³ The denominators of MI and CS are not strictly equivalent to the 1965 city population because they exclude: (a) 1965 city residents who have not survived until the end of the 1965–70 interval; (b) 1965 city residents who have migrated out of the metropolitan area over the course of the interval. Each of these exclusions was made for the practical reason that they could not be identified from our data source (migration tabulations from the 1970 census) described below. The first exclusion tends to slightly understate mobility levels because migrants, by virtue of their younger age structure, enjoy a greater probability of survival of the interval than nonmigrants.

The second exclusion can be justified on theoretical work which suggests that out-migrants from the metropolitan area cannot be considered local movers in the usual sense because their *migratory* moves are motivated largely by economic attributes that characterize the entire metropolitan (or labor market) area (Lansing and Mueller, 1967; Speare et al., 1975). Since local moves within the metropolitan area are not substitutable for these, one can argue that it is not appropriate to include out-migrants in the at-risk population for local mobility rates (if one move per individual is recorded during the interval). Frey (1978a) provides further elaboration on this point.

ity through each of the two stages in a path analysis.

One further refinement needs to be made in our analytic model: an adjustment for the relative proportion of the SMSA population which resides outside the central city. In our comparisons of MI, SP, and CSM rates among 39 SMSAs, it should come as no surprise that somewhat of a tautological relationship exists between the suburb/SMSA population ratio and the suburban propensity rate of central city movers. This ratio, in effect, serves as a crude proxy for the proportion of SMSA destination opportunities that exist in the suburbs. Because the purpose of this study is directed to evaluating the relative effects of various social and economic explanations for mobility, it is desirable to control for this relationship.

We therefore compute an adjusted suburban propensity rate (SP') which is defined as:

$$SP' = \left(\frac{SP}{\left(\frac{\text{suburb population 1965}}{\text{SMSA population 1965}} \right)} \right) \times K, \quad (6)$$

where K = mean value of the 1965 suburb/SMSA population ratio for the 39 SMSAs.

Since the city-to-suburb stream mobility rate is defined as the product of the mobility incidence and suburban propensity rates, an adjusted city-to-suburb stream rate (CS') is computed such that:

$$CS' = MI \times SP'; \quad (7)$$

$$\log CS' = \log MI + \log SP'. \quad (8)$$

Values for the rates just presented are based on tabulations in the *Mobility for Metropolitan Areas* subject report of the 1970 census (U.S. Bureau of the Census, 1973a). For each SMSA, these tabulations identify the reported 1965 city, suburb, and outside SMSA residence locations of 1970 city or suburb residents, aged 5 and above. 1970 city residents who reported living in the same dwelling unit as 1965 are also identified. Using these data, we can estimate rates (1), (2), (3) and (6) for individuals residing in each study SMSA in

both 1965 and 1970. (The reader interested in the computational details is referred to Frey [1978a].) It should be noted that the census tabulations do not identify multiple movers, return movers, or emigrants from the U.S. over the course of the five-year interval. Also, a significant minority of 1970 metropolitan residents (an average of 6.6% for the SMSAs in this study) are classed as "moved but previous residence abroad or not ascertained." These individuals were not included in the mover categories associated with the above rates.

Making use of the additive relationship (8), we first of all regress the natural log of the adjusted city-to-suburb stream rate on its two component rates for the 39 SMSAs in the study. This yields the following:

$$\log CS' = +1.0 MI + 1.0 \log SP', \\ (+.343) \quad (+.741) \quad (9)$$

where the values in parentheses are standardized regression (β) coefficients. The R^2 for this regression equation equals 1.00; hence, we are able to assess the relative variation, across SMSAs, attributable to each component of the city-to-suburb stream mobility rate by comparing their standardized regression coefficients. It can be seen that the coefficient associated with the suburban propensity component is considerably larger than that associated with the mobility incidence component. This suggests that levels of residential mobility tend to be fairly uniform among the resident populations of cities and that city-specific factors which exert greatest influence on the size of the city-to-suburb stream primarily affect the destination selection stage of the process.

Equation (9) represents the initial step in the construction of a path model that will be employed to examine the impact of different causal factors on city-to-suburb stream mobility through its two components. The model will allow us to identify each causal factor's effect for the purpose of evaluating the first hypothesis raised above. In addition, it will permit us to decompose each factor's total effect on $\log CS'$ into that directed through the mobility incidence component ($\log MI$) and

that directed through the suburban propensity component (log SP'). Since the latter component represents the "movers' destination selection" stage of the mobility process, this decomposition of effects will enable us to evaluate the second hypothesis raised above.

The analysis will occur in three parts: first, the relationship between log MI and various causal factors will be estimated in a regression analysis; second, the relationship between log SP' and appropriate factors will be estimated in a similar manner; and third, the total effects and decomposition of effects attributable to each causal factor will be computed from a path model constructed from the regression equations. Before proceeding with the analysis, we introduce the several city and SMSA attributes which will serve as causal factors.

CAUSAL FACTORS TO BE EVALUATED

The city and metropolitan attributes to be evaluated in this study represent measures of factors discussed above, whose relationships to white city-to-suburb movement have been subject to debate among urban scholars and policy analysts. One set of factors are intended to measure the independent racial effects on white out-movement from the city. If, as has been suggested, the increased exposure of whites to blacks results in their further flight from the center core, policies which serve to bring about such exposure will no doubt be subjected to closer scrutiny by city officials. A second set of factors is linked to the contention that central city decline itself has effected a continued out-migration. Several urban analysts have maintained that a feedback effect is occurring wherein the current selective out-movement from financially plagued cities contributes to a further tax base erosion and environmental deterioration in the central core and, hence, sets the stage for continued residential evacuation in the future (Bradford and Kelejian, 1973; Peterson, 1976; Clark et al., 1976). According to this view, an emphasis on racially-motivated central city out-migration would appear to be misplaced. Finally, a third set of factors not generally

mentioned in current discussions of white flight determinants will be considered in the present analyses. These include features of the metropolitan area's demographic structure which exert a strong influence on intra-SMSA movement patterns. Such attributes need to be taken into account if an accurate evaluation of the more interesting policy-relevant factors is to be made.

The analysis below evaluates the white migration effects associated with the three headings "factors related to race," "factors related to central city decline" and "factors related to population structure." These are listed in Appendix A along with their sources.⁴ The ten attributes were selected as a result of preliminary analyses, in which alternative indicators for several of the causal factors were examined. In the remainder of this section we present a brief rationale for each causal factor included and discuss its expected relationship with white city-to-suburb mobility.

Factors Related to Race

The first race-related factor, Percent City Black (i.e., the percent of the city population which is black), indicates the relative presence of blacks vis-à-vis the total population for each central city in the

⁴ It will be noted that many of the causal factors are based on 1970 measures. Although this practice introduces a potential simultaneity bias into our findings, we are bound by the constraints of available data. Census data for metropolitan population and housing characteristics are collected at ten-year intervals and only the 1970 characteristics are consistent with the city and suburb boundaries to which the mobility data pertain. This consideration also applies to the fiscal variables we employ. The data base prepared for the Advisory Commission in Intergovernmental Relations (1973: Appendix B) represents the only source, to our knowledge, which constructs SMSA city-suburb tax and educational expenditure disparity measures for each of the metropolitan areas in our study, based on boundaries which coincide with those in the census migration reports. To the extent it exists, simultaneity bias should operate to overestimate the effects of the factors, Postwar Suburban Development, Percent City Black, Suburb/City Per Capita Taxes, and Suburb/City Per Capita Educational Expenditures. However, an examination of the simultaneity effects associated with the first factor (discussed below) indicates that they are minimal.

study. As discussed earlier, the conventional wisdom which hypothesizes a positive relationship between Percent City Black and white city-to-suburb movement is rooted in the neighborhood racial transition literature of the 1950s. Its potential significance was pointed up more recently in the context of post-Kerner Commission debates over the migration consequences associated with instituting "ghetto enrichment" programs—interim measures aimed at improving the quality of life and increasing employment opportunities for central city blacks until more widespread "ghetto dispersal" could be effected (National Advisory Commission on Civil Disorders, 1968; Harrison, 1974). Critics of the enrichment strategy have contended that it would provide incentives for the continued city concentration of blacks (through in-migration from outside the metropolitan area) and that the visibility of such concentration would further discourage white residences and businesses from locating in the central core. In this vein, Kain and Persky (1969:75) write:

The central Negro ghetto has produced a significant distortion of metropolitan development. . . . The decline of central cities has been hastened by a conviction in the white community, both individual and corporate, that the ghetto would continue its rapid expansion, carrying along its associated problems of concentrated poverty and social disorganization.

To test the conventional wisdom and determine if, in fact, increased exposure to blacks does affect white city-to-suburb movement apart from other causal factors, we incorporate Percent City Black in the multivariate analyses that follow. In preliminary analyses, we attempted to refine our measure of black contact by including, in addition to Percent City Black, an index of central city racial segregation (the index of dissimilarity), and an interaction term based on this index and the factor, Percent City Black. None of these analyses resulted in substantial increases in the variance explained. Moreover, the effects on white city-to-suburb movement in individual SMSAs that could be attributed to the combination of these measures did not differ appreciably with those associated with Percent City Black when it

alone was included. The single measure was therefore chosen for reasons of parsimony.

The second race-related causal factor, School Desegregation, is a measure of change in racial segregation that occurred within central city public elementary schools over the period 1967–72. The importance of desegregation in the public schools for central city out-movement of white children and their parents is suggested in a study by Coleman et al. (1975) which examined white school enrollment changes for 67 central city school districts over the period 1968–73. The authors found a significant relationship to exist between intradistrict school desegregation and white school enrollment losses among central city districts. Moreover, increases in city-suburb *between district* racial segregation were found to occur in SMSAs whose central city districts had undergone substantial within-district desegregation. Other studies using similar data but focusing on different universes of districts and/or observation years have yielded conflicting results (see Pettigrew and Green, 1976a, and Snyder and Kelly, 1977, for a critical review of these).

Virtually all of the studies which have tested the school desegregation white flight hypothesis have examined desegregation effects on school enrollment losses, not on out-migration patterns. Slippage between the two can result from the tendency for white pupils to switch to private schools while still residing within the district. Nevertheless, a linkage between central city school desegregation (occurring in isolation of metropolitan wide practices) and white out-movement has been suggested by Coleman (1976:12):

. . . the present policies of school desegregation which focus wholly on within-district segregation exacerbate the already unstable ecology of our large cities. They are increasing rather than reducing or reversing the tendency for our large metropolitan areas to come to consist of black central cities and white suburbs.

This implied relationship between central city school desegregation and overall white city-to-suburb movement will be examined here.

Unfortunately, the period to which our migration data pertain is not the most appropriate one to capture this effect for two reasons. First, the Office of Civil Rights data used to compute district segregation change measures in this and other studies were only first collected in 1967. Hence, segregation indices which take into account school segregation levels at the beginning of the migration period cannot be constructed. Second, although a number of desegregation actions had been initiated in northern city districts prior to 1970 (Rossell, 1975), those most likely to elicit a white response (i.e., the reassignment of white students to predominantly black schools) did not become prevalent until the fall of 1971.⁵

In preliminary analyses, we examined the white city-to-suburb movement effects associated with three measures of school segregation change: (1) difference between the 1967 minus 1970 value of the index of dissimilarity computed for city elementary school students; (2) difference between the 1967 minus 1972 value of the index of dissimilarity computed for city elementary school students (i.e., the measure described in Appendix A); and (3) a dummy variable indicating a value of 1.0 if a district's index of dissimilarity decreased ten or more points over the course of the 1967-72 period, and a value of zero otherwise. Measures (2) and (3) take cognizance of the more prevalent northern desegregation which occurred in the immediate post-1970 period as it is reasonable to assume that white city-to-suburb movement prior to 1970 may have been influenced by the prospect that widespread desegregation would be taking place in affected city districts. The preliminary findings revealed a slight negative relationship to exist between measure (1) and white city-to-suburb movement, indicating that pre-1970 desegregation exerted a negligible influence independent of other causal factors. Each of the latter two measures yielded a stronger positive relationship with white suburbanward movement, and measure (2), the continu-

ous variable, was chosen as the superior measure of change.

Because several of the aforementioned school enrollment decline studies find the school desegregation white flight effect to be heightened in city school systems with large black enrollments, we performed still another analysis in which our change measure (2) was weighted by the black proportion of city elementary students in 1970. Our findings from this investigation indicate that white city-to-suburb residential flight is no more responsive to this weighted measure than it is to measure (2) alone. (Indeed, the weighted measure exhibited negative, though insignificant, effects on both white mobility incidence and the suburban propensity of white city residents when incorporated into the equations presented below.) On the basis of these results, therefore, we decided to retain measure (2) as an index of school desegregation. It nevertheless should be emphasized that our analysis does not take into account desegregation effects on post-1970 population movement. Hence, our results for this factor must be considered as only suggestive of those that would be obtained if appropriate migration data were available.

The third race-related factor, Incidence of Racial Disturbances, measures the rate at which racial disorders broke out in the central city in the late 1960s. Although scattered racial riots and disorders have occurred in earlier periods, the Kerner Commission, choosing to view racial disorders of the 1960s from a national perspective, attributed a number of contributing ingredients to a more pervasive "white racism" which has been developing in large cities since the end of World War II. Spilerman tested a range of hypotheses in an attempt to account for the location of these racial disorders and concluded that the latter were "responses to frustrations which are uniformly felt by Negroes, irrespective of their community situations" (Spilerman, 1970:627).

Although an explanation of the riots does not seem to lie with community-specific causes, riot-prone communities have experienced negative effects including: recurring disorders, increased distrust between blacks and whites, less interra-

⁵ We are grateful to Christine Rossell for calling this to our attention.

cial communication, and the growth of white segregationist or black separatist groups (National Advisory Commission on Civil Disorders, 1968:151). Increased suburbanward flight may represent another response to the prevalence of racial disorders in a city. Such a response would be significant for future movement patterns in ghetto-ridden cities since according to the Kerner Commission, a possible consequence of accelerating aid programs to urban ghettos may be short-term increases in disorder activity resulting from the unfulfilled expectations of program recipients. The measure, incidence of racial disturbances, used here employs data collected by Spilerman (1970) on instances of racial violence involving 30 or more individuals that were initiated by aggression on the part of blacks. In preliminary analyses, we used the *number* of racial disturbances as an alternative to the incidence measure and found its influence on the migration variables to be no greater in magnitude. Moreover, they were inconsistent—exerting a negative (though insignificant) effect on white mobility incidence and a positive effect on white suburban propensity. On the basis of these findings we chose to employ the incidence measure in our analysis below.

Factors Related to Central City Decline

The decline of the central city relative to its suburbs in terms of residential costs, services and social environment can be translated into several specific dimensions. In this study, we focus on factors which have previously been posited as determinants of out-migration. Two of these—the suburb/city ratio of per capita tax revenues, and the suburb/city ratio of per capita educational expenditures—reflect cost and amenity comparisons which potential movers can assess in dollars-and-cents terms. The inclusion of both these factors in the following multivariate analysis will allow us to evaluate the proposed feedback relationship between city-suburb fiscal disparities and suburbanward out-movement. Since metropolitan areas differ on the degree to which local sources contribute to overall tax revenues and education expenditures,

the measures we employ for each of these include total revenues and expenditures attributable to local and nonlocal government levels.

Values for the first ratio, suburb/city per capita taxes, are less than 1.00 in 36 of the 39 SMSAs in this analysis, a finding which coincides with our earlier discussion of central cities' fiscal difficulties. To the extent that a greater city tax burden represents an incentive for suburbanward movement, a negative relationship between this ratio and the migration measures is expected.

Values for the second ratio, suburb/city per capita educational expenditures, are greater than 1.00 in 30 of the 39 SMSAs. Since the quality of a community's school system provides a particular attraction for households with children and residential mobility rates are generally high among families with children in the preschool ages (Long, 1972), the suburb/city per capita educational expenditure ratio is expected to exert an independent, positive effect on suburbanward relocation. In preliminary analyses, we examined the effects of an alternative measure, suburb/city per pupil educational expenditures, as an indicator of this factor and found its relationship to the mobility variables to be less impressive. Although neither measure is an ideal indicator of relative school quality, the poorer performance of the latter might be attributed to its tendency to overstate the quality of city schools since a disproportionate amount of city expenditures goes into vocational programs and special education for disadvantaged students (Pettengill and Uppal, 1974).

The City Crime Rate constitutes a third central city decline-related factor which is often posited as a flight determinant (Orfield, 1976). Due to past suburbanization and fixed political boundaries, many cities tend to house disproportionate numbers of those population subgroups which are subject to high arrest and victimization rates (President's Commission on Law Enforcement and Administration of Justice, 1967). Yet at least two empirical studies yield results which counter the commonly held view that the city crime rate is linked to increased suburbanward relocation (Droettboom et al., 1971;

Guterbock, 1976). The Droettboom et al. findings, in particular, indicate that moves associated with the perception of crime in the city are undertaken to a great extent by low-income individuals and are more likely to result in a within-city relocation rather than movement to a suburban destination. This study, an analysis of nationwide survey findings, does not take cognizance of competing explanations for mobility patterns. The present analysis will evaluate the independent mobility effects associated with the city crime rate when other relevant factors (such as the city's racial composition) are taken into account.

The crime rate measure employed here is based on the number of crimes that are reported in the city per 1,000 city population. Although Gibbs and Erickson (1976) contend that such a rate might be deceptively large because the denominator (city population) does not include potential noncity victims or offenders, we would argue that this rate more accurately represents the *perception* of crime among city residents and therefore remains a useful measure for purposes of the present investigation.

The fourth central city decline-related factor to be evaluated as a mobility precipitant pertains to the suburban relocation and expansion of employment opportunities. As mentioned earlier, it has been posited that the relatively recent dispersal of blue-collar jobs in many metropolitan areas ultimately will affect the residence and/or workplace distributions of present central city residents. To the extent that central city worker-residents are unable to locate alternative city jobs two responses (in addition to unemployment) are possible: (1) increasing rates of "reverse" city-to-suburb commuting; or (2) increasing rates of city-to-suburb residential mobility. Aggregate work-residence patterns for the 1960-70 decade suggest that both responses were prevalent among central city whites during the period (Guest, 1975a; Kasarda, 1976). However, the residential mobility literature provides mixed evidence regarding the immediate impact of employment relocation on local mobility decisions (Goldstein and Mayer, 1964; Roistacher, 1974; Goodman, 1974;

Guest, 1975b). In this study, we shall use the percent of city workers who commute to the suburbs (City-Suburb Commuters) as a proxy for recent job decentralization and examine its posited direct relationship with white movement to the suburbs.

Factors Related to Population Structure

The factors described under the previous two headings are continually being suggested as potential causes of central city population loss via the out-migration route in recent writings of urban scholars and policy analysts (see contributions in Sternlieb and Hughes, 1975; 1978; Gorham and Glazer, 1976; Leven, 1978). Such discussions often do not take explicit account of factors associated with a metropolitan area's demographic structure which are far less amenable to short-term alterations but nevertheless exert a strong and continuous influence on intrametropolitan redistribution processes. It is desirable to control for the effects of these latter factors in a multivariate analysis in order to provide an accurate evaluation of policy relevant factors whose effects on population mobility may be of more immediate interest. The present analysis will incorporate measures for three such factors: one which controls for the effect of recent intrametropolitan growth patterns, and two measures of central city population and housing composition which have been shown to influence levels of mobility incidence among city residents.

Postwar Suburban Development, the first population structure-related factor, measures the recency of a metropolitan area's suburban development. Policy discussions of race-related and central city decline-related migration determinants, alluded to above, tend to focus on metropolitan areas which greatly overlap with respect to demographic structural features and growth history. These are generally older areas in the Northeast and North Central regions with high central city population densities. Most have been decentralizing in population since early in the century and have undergone actual central city population losses since 1950.

In contrast, there exist a large number

of expanding, low density metropolitan areas, located primarily in the South and West, whose central cities and suburbs have developed more recently. Due to their ability to annex territory to the political city boundaries, the central cities of these newer SMSAs are not as "under-bounded" as those in older, more densely populated metropolitan areas and their population and housing characteristics are not as greatly differentiated from those of the suburbs (Schnore and Winsborough, 1972; Guest, 1972; Kaufman and Schnore, 1975; Kasarda and Redfearn, 1975). The high level of suburban growth displayed by these areas in the post-1950 period approximates a natural expansion of the city periphery which now-declining areas experienced decades ago.

Because the pattern of development and suburbanization recently experienced by the latter areas is likely to characterize redistribution processes during the period under observation here, we include the factor, Postwar Suburban Development, to control for such patterns. It is operationalized as the percent of 1970 suburban year-round units in structures built since 1950⁶ and is expected to relate

positively to city-to-suburb movement levels. This factor was chosen among alternative measures of demographic structure and growth histories that have been employed by other analysts: age of the city; central city population density, manufacturing ratio of the central city, and geographic region (Schnore and Winsborough, 1972). Although one of these measures tended to be correlated with Postwar Suburban Development (zero-order correlations with each of the first three were stronger than $-.44$), these structural features are further removed, in a causal sense, from the redistribution process. This was confirmed in preliminary analyses which showed Postwar Suburban Development to exert stronger effects on city-to-suburb mobility than those exerted by the other measures.

The final two factors related to population structure are Percent City Owners, and City Age Distribution. Each controls for the compositions of central city residents with respect to factors that previous research suggests are strong determinants of residential mobility incidence at the individual level (Rossi, 1955; Speare, 1970; Speare et al., 1975). Percent City Owners, the percent of white (nonblack) city residents of self-owned units, is expected to relate negatively to the mobility incidence among white residents. City Age Distribution measures the percent of city nonblack residents in the most highly mobile age groups and is expected to relate positively to their mobility incidence. Unlike the other eight causal factors in this study, which will be evaluated as determinants for both components of the city-to-suburb mobility stream, Percent City Owners and City Age Distribution will be evaluated only as determinants of the mobility incidence component.

ANALYSIS

To follow the analysis strategy outlined earlier, we shall examine the effects of the various causal factors on our measures of white city residents' mobility incidence,

⁶ At a reviewer's suggestion, we have looked into the possibility that the city-to-suburb mobility measure which represents our dependent variable may be systematically related to the Postwar Suburban Development factor (i.e., that the construction of suburban dwelling units during the 1965-70 period may have been due to the demand of 1965-70 city-suburb movers). In response we estimated, for each SMSA, a hypothetical measure of Postwar Suburban Development intended to eliminate the possible effects of city-to-suburb movers, given the extreme assumption that all households in the white 1965-70 city-to-suburb stream locate in 1965-70 constructed dwelling units. (This hypothetical Postwar Suburban Development measure differs from the actual measure defined in Appendix A in that the former eliminates the number of households in the white 1965-70 city-to-suburb stream from both numerator and denominator.) The computed values for the hypothetical measures differ only slightly from those of the actual measures for individual SMSAs since suburban dwelling unit construction responds to other sources of demographic change aside from city-suburb mobility (i.e., out-migration from the suburbs, in-migration from outside the SMSA, household formation in the suburbs). Moreover, in estimating regression equations 4 in Table 1, and 4 in Table 2 based on these hypothetical measures, we find only a slight diminution of effects associated with Postwar Suburban Development (from β values of $+.593$ to

$+.573$, and from $+.529$ to $+.509$, respectively) and minimal changes in the effects of other causal factors.

and white city movers' suburban propensity (log MI and log CS' as defined earlier) in separate regression analyses. The results will then be incorporated into a path analysis to determine the effects of each causal factor on the log of the white city-to-suburb stream mobility rate (CS'), and test the two hypotheses raised at the outset.

An intercorrelation matrix for the causal factors employed in the following regression analyses is presented in Appendix B. An examination of the correlation coefficients suggests that our models will not be subject to high levels of multicollinearity and its associated problems. Of the 45 coefficients among the ten factors, none indicate relationships as strong as $\pm .50$ and only seven are stronger than $\pm .30$. One association which was not unanticipated is the $+.41$ correlation between Percent City Black and the City Crime Rate. The implications of this relationship for our findings are discussed below.

Causal Factors and Mobility Incidence

Presented in Table 1 are four equations in which the log of the mobility incidence rate (log MI) is regressed on the various categories of the causal factors: popula-

tion structure factors (equation 1); population structure and race-related factors (equation 2); population structure and central city decline factors (equation 3); and factors for all three categories (equation 4). These equations allow us to evaluate, first, the effects of population structural factors on mobility incidence, and second, the effects of factors in the more policy-relevant categories when population structure is taken into account.

It is clear, from examining all four equations, that white city residents in the recently developing SMSAs experience higher levels of mobility incidence. The beta (β) coefficient values for Postwar Suburban Development are consistently large whether or not factors related to race or central city decline are included in the equation. The effects of the compositional factors, Percent City Owners and City Age Distribution, on mobility incidence are less impressive than we were led to expect on the basis of existing literature. Our findings do indicate that cities with more self-owned (and presumably single-family) dwelling units tend to exhibit lower levels of mobility incidence among their white residents. The impact of the city's age composition on mobility incidence levels, however, is not as strong according to the β values in Table 1. It is

likely that the effects of the latter two compositional factors are diluted to some degree by their moderately strong correlations with Postwar Suburban Development. Nevertheless, a comparison of the R^2 values in equation 1 with those in equations 2, 3 and 4 indicates that these three population structural factors account for a substantial share of inter-SMSA variation in mobility incidence, and suggests that their inclusion as controls in this evaluation of race-related and central city decline-related factors is justified.

Our contention that the mobility incidence effects associated with the race-related factors in this analysis would be small is given support in the Table 1 equations. The additional variance explained in equation 2 over equation 1 is minimal and the Beta coefficients for School Desegregation and Racial Disturbances in equation 4 are among the smallest of all the causal factors in the analysis. Even the effects for Percent City Black, a measure thought to be associated with increased flight levels, show up to be relatively small when other demographic structure and central city decline-related factors are taken into account. (Its .068 Beta coefficient value in equation 4 can be compared with the +.136 value in equation 2 which does not take account of central city decline factors, and its zero-order correlation with the log of MI of +.200.) In contrast, the Beta coefficients associated with the Suburb/City Per Capita Tax Ratio, and City-Suburb Commuters, indicate that these central city decline factors exert nontrivial influences on city mobility incidence levels. The magnitudes of their effects do not change appreciably whether or not race-related factors are included in the equation. Moreover, a comparison of the R^2 values in equations 1 and 3 indicate that, unlike the race-related factors, the block of central city decline-related factors contribute substantially to the percent of variance explained above that which can be attributed to population structure.

In sum, these regression equations indicate that the factors associated with metropolitan population structure explain a good deal of inter-SMSA variation in the mobility incidence of white city residents. Additional independent effects can be at-

tributed to measures of city-suburb fiscal, and residence-workplace disparities when population structure has been taken into account. However, the small effects that are attributable to each of the race-related factors, when controls for other mobility determinants are instituted, do not lend support to the view that a greater exposure to blacks can be linked to substantial increases in the incidence of mobility among central city whites.

Causal Factors and Suburban Propensity

The regression equations that were estimated to examine the effects of each of the causal factors on the log of the white suburban propensity rate ($\log SP'$) are presented in Table 2. Here, as in Table 1, the four equations permit an evaluation of population structure effects alone, and effects associated with race-related, and central city decline-related factors when population structure is taken into account.

In these equations the single population structure factor, Postwar Suburban Development, again shows up to have an important influence on mobility patterns. Its effect, as indicated by the β values in Table 2, is strong and consistent in all four equations. It appears, therefore, that white city residents in recently developed SMSAs are not only more likely to move (as was demonstrated in the analysis of mobility incidence) but that such moves are more apt to be destined toward the suburbs.

Turning to the more policy-relevant factors in the analysis, we find that race-related factors exert a more formidable influence on the suburban destinations of white city movers than they exerted on the mobility incidence of white city residents. A comparison of the R^2 values in equations 1 and 2 shows that the block of race-related factors accounts for a considerable increase in the variance explained above that attributable to demographic structure alone. The Beta coefficient values associated with Percent City Black indicate that its strong positive effect on white suburban propensity is not appreciably reduced when factors related to central city decline are included in the equation, and that the magnitude of its

effect is at least as important as those associated with city-suburb fiscal disparities. In contrast, the suburban propensity effects for the two remaining race-related factors, School Desegregation and Racial Disturbances, are fairly minimal when other mobility determinants are taken into account.⁷

The importance of central city decline-related factors toward the explanation of white city movers' suburban propensity is also apparent from the equations in Table 2. As with the race-related variables, these factors contribute substantially to the variance explained by the population structure variables alone (based on a comparison of the R² values in equations 1 and 3). Moreover, the Beta values in equation 4 indicate that strong effects in expected directions can be attributed to

three of the four central city decline factors, Suburb/City Taxes, Suburb/City Educational Expenditures and City-Suburb Commuters. Although the β value associated with the fourth factor, the City Crime Rate, tends to be large in equation 3, the incorporation of the race-related factors substantially diminishes its effect. (In order to examine the extent to which the correlation between the city's social composition and crime rate might influence the results in equation 4, if one or the other was not included, we recomputed two alternative equations—each leaving out one of these two factors. We found that when the City Crime Rate factor was omitted from equation 4, the β value associated with Percent City Black increased from +.377 to +.422. When Percent City Black was left out of the equation, the +.115 Beta coefficient for City Crime Rate was increased to +.266. In each case the new β coefficients were larger than twice the values of their standard errors.)⁸

⁷ In addition to the reported findings, we examined the possibility that the socioeconomic characteristics of the city black population might exert an independent effect on white suburban propensity rates. In two separate analyses, we incorporated one of the following variables, Percent of City Blacks (age 25 and over) with 0-8 years of schooling, and Percent of City Blacks living in families with annual incomes less than \$6,000, in addition to those already included in equation 4 of Table 2. Findings from these investigations indicated that contributions to R² associated with each of these factors were negligible, their standardized regression (β) coefficients were relatively small (+.017, +.032), and their respective regression coefficients were far smaller than their standard errors.

⁸ In still another analysis, we retained in the equation both the Percent City Black and City Crime Rate factors, and added an interaction term defined as their product (Percent City Black \times City Crime Rate). The R² value for this equation (.609) was only slightly larger than that for equation 4 in Table 2, and the relatively small β coefficient associated with the interaction term was negative (-.070). Moreover, when the interaction term is included, the regression coefficients for that term, City Crime Rate and Percent City Black were all less than twice the values of their respective standard errors.

The preceding regression analyses indicate that aside from the strong influence of population structure, both the city's racial composition and factors symptomatic of central city decline—city-suburb fiscal disparities and the suburbanization of employment opportunities—exert independent effects on the suburban relocation patterns of white city movers in expected directions. In light of our earlier discussion, the magnitude of effect linked to the city's racial composition is somewhat surprising and would appear to discount our assertion that this effect would be minimal when factors related to central city decline are taken into account. These findings, however, pertain only to the suburban propensity stage of the mobility process. A more accurate assessment of each causal factor's effects on white city-to-suburb mobility can be made from the analysis that follows.

Causal Factors and City-to-Suburb Mobility

We can now proceed to evaluate the effects of each causal factor on the log of the city-to-suburb stream mobility rate (log CS') by constructing a path model wherein the relationships between the ten causal factors, and the log of the city-to-suburb stream rate are directed through the logs of its two component rates, the mobility incidence rate and the suburban propensity rate (log MI and log CS' as presented in equation [8]). A diagram of the path model based on the standardized regression (β) coefficients in text equation (9), Table 1 equation 4, and Table 2 equation 4, appears as Figure 1. Because the variation in log CS' is completely determined by variations in log MI and log SP', no direct relationships exist between the ten causal factors and log CS', or in other words, our model forces all relationships between the causal factors and the city-to-suburb mobility measure (log CS') to operate through the measures of mobility incidence (log MI) and/or the measure of suburban propensity (log SP'). (See Winsborough's path model in Duncan [1971] for a similar application of this technique to a different problem.)

In order to evaluate each factor's con-

tribution to SMSA variation in log CS' given the path model in Figure 1, we employ the decomposition of effects technique proposed originally by Duncan (1971) and elaborated upon by Alwin and Hauser (1975). The "total effects" (using the terminology of the latter authors) for each causal factor are determined by summing the products of all possible paths between that factor and the dependent variable, log CS'. Since there are no direct paths between each factor and CS', no "direct effects" can be computed from our model. The total effects associated with each causal factor, therefore, represent the sum of two "indirect effects": those through log MI (the path coefficient connecting the factor and log MI, multiplied by +.343) and those through log SP' (the path coefficient connecting the factor and log SP' multiplied by +.741). A summary of each factor's total effects on SMSA variation in log CS' as well as its indirect effects through log MI and log SP' is presented in Table 3.

We can now return to the hypotheses raised at the outset. Our first concern was with the validity of various racial and non-racial explanations for the city-to-suburb movement of whites. It was our contention that factors related to race would be of lesser importance than those related to central city decline. The effects shown in column (1) of Table 3 do not support this assertion. Aside from the large effects attributable to Postwar Suburban Development, one of the factors which controls for the metropolitan area's population structure, the out-movement effects associated with the central city's racial composition (Percent City Black) are similar in magnitude to the strongest central city decline-related effects. Effects for the two other race-related factors, School Desegregation and Racial Disturbances, are far less impressive. These factors would appear to represent minor, if not negligible influences on white residential out-movement. As we expected, central city decline-related factors are prominent in accounting for SMSA variations in white city-to-suburb stream movement. All four of these factors influence movement in expected directions with strongest effects being attributable to our measure of recent

Figure 1. Path Diagram Relating Causal Factors to Log CS' through Log MI and Log SP' (Based on Equation 9 in Text, Equation 4 in Table 1, and Equation 4 in Table 2)

Table 3. Decomposition of Effects for Causal Factors on SMSA Variation in Log CS' (Based on Path Diagram in Figure 1)

Causal Factors	Total Effects on SMSA variation in Log CS' (1)	Effects through:

City-Suburb Commuters	+.316	+.138	+.178

employment suburbanization (City-Suburb Commuters) and city-suburb tax and educational expenditure disparities.

In the second hypothesis, we expected that racial factors—to the extent that they influence city-to-suburb stream mobility—would operate primarily through the destination selection process of movers. This hypothesis can be evaluated by examining the extent to which each factor's total effects on log CS' (in column [1] Table 3) are directed through log SP' (in column [3] Table 3)—the suburban propensity component of the log of the city-to-suburb mobility stream rate. The data in Table 3 show clearly that our second hypothesis is confirmed not only for factors related to race, but for *all* factors which are causally linked to log CS' through both log MI and log SP' (the factors Percent City Owners and City Age Distribution are linked only through log MI). Furthermore, when one focuses only on effects directed through the mobility incidence component, log MI (column [2]), it can be seen that effects associated with the Percent City Black are dwarfed by those attributable to central city decline factors, City-Suburb Commuters and Suburb/City Taxes.

Finally we wish to underscore the point, made obvious above, that it is important to take cognizance of a metropolitan area's population structure in multivariate analyses directed to assessing the effects

of more short-term influences on residential mobility patterns. The consistently large effects associated with our measure of recency of suburban development (Postwar Suburban Development) in each of the regression analyses and in the decomposition of effects analysis supports our claim that an SMSA's current redistribution patterns are shaped, in part, by its recent growth history as well as by slowly changing ecological and demographic features of the area.

CONCLUSION

We began this investigation by advancing two hypotheses that are relevant to understanding both why and how recent city-to-suburb movements of whites in large metropolitan areas have taken place. In the first, or "why" hypothesis, we expected that racially-linked city attributes such as residential racial composition, the incidence of racial disorders or an increase in school desegregation would be less likely to affect the out-movement of whites than attributes which reflect the social and economic decline in the central city relative to the suburbs.

Our findings do not allow us to discount the racial composition of the central city as a predisposing factor toward white suburbanward movement. Although we would have been prone to argue that a strong zero-order correlation between a

city's black population percentage and its level of white out-movement might mask other mobility-inducing features of cities with large concentrations of blacks such as higher taxes or greater crime rates, our findings, which control for these factors, do not lend support to this view. Strong mobility effects, however, are not found to be associated with cities that had undergone recent desegregation of public schools or those which had been subject to racial disturbances during the late 1960s. As we have noted earlier, the weak relationship between the former factor and white out-movement may not yet be definitive since a good deal of northern school desegregation that entailed two-way bussing took place subsequent to the 1965-70 migration interval under investigation here.

Although the racial influences fared better than we expected, we find the mobility of whites to be just as responsive to various dimensions of central city decline—city-suburb fiscal disparities, particularly relative tax levels, and also to the degree to which employment has suburbanized. The data also show a substantially greater out-movement of whites from metropolitan areas where there has been considerable postwar suburban development. These, however, are usually newer and more rapidly growing areas with large counterstream movements *into* the city that tend to balance out the central city flight.

In the second, or "how" hypothesis, it was anticipated that racial influences on white city-to-suburb mobility would operate primarily through the selective destination choices of movers rather than through their decisions to move. Our data strongly supported this expectation for both racial and nonracial causes. This insight into the dynamics of intraurban mobility portends some short-term optimism for the plight of the declining central city. It suggests that deteriorating economic and social conditions in the core will not precipitate a wholesale evacuation of current residents but will primarily affect the destination selections of that continually-present mover pool which comprises a relatively constant proportion of the total population from city to city. To the extent

that racial factors proved to be negligible in explaining the incidence of mobility across SMSAs, we conclude that the term *white flight* is an inappropriate description of the suburbanward movement of city whites.

This study was undertaken to shed light on the residential white-flight impacts often attributed to proposed policies such as ghetto enrichment programs for inner city minorities and central city school desegregation, in order that we might clarify the role of racial factors in this movement. Although our first hypothesis was not confirmed, the findings here do not support the view that increases in the numbers or levels of integration of central city blacks will have a substantial effect on white out-movement in the short-term. Hence programs aimed at achieving higher standards of living and better schooling for central city minorities might be implemented without precipitating immediate white population losses.

Despite this mildly optimistic implication of our analysis, we have uncovered no easy remedies toward decreasing the level of white out-movement which is presently taking place. The fiscal crisis in big city government as well as the suburbanization of employment opportunities and residences are likely to continue, particularly in the already declining central cities of our older metropolitan areas. The resulting increase in disparities between cities and their suburbs in services offered and taxes levied is likely to become even more important in the future mobility decisions of central city residents, than was shown during the 1965-70 period.

There may be some truth to Gorham and Glazer's (1976:28) less than optimistic prognosis that:

The declining cities are going through a period of urban natural selection. The most likely outcome: some will pull out, stabilize and even revitalize; others will continue to weaken and eventually stabilize at a much lower level of activity.

Given this situation, central cities must look beyond their own political boundaries to obtain the resources necessary to increase their attractiveness for residents and industry.

APPENDIX A

DEFINITIONS AND SOURCES OF CITY AND SMSA ATTRIBUTES TO BE EVALUATED AS CAUSAL FACTORS OF WHITE CITY-TO-SUBURB MOVEMENT

Factors Related to Race

Percent City Black

Percent of total 1965 city population which was black. 1965 totals were averaged from 1960 and 1970 totals.

Source: U.S. Bureau of the Census, 1973b.

School Desegregation

Difference between the 1967 minus 1972 values of the index of dissimilarity computed for black and nonblack elementary school students across schools within the central city district.

Source: U.S. Commission on Civil Rights, 1967; 1974.^a

Incidence of Racial Disturbances

The number of spontaneous outbreaks characterized primarily by Negro aggression which took place in the city between 1965-68, per 100,000 central city population, 1965.

Sources: Lemberg Center for the Study of Violence, 1968a; 1968b; Congressional Quarterly Service, 1967. *The New York Times Index*.^b

Factors Related to Central City Decline

Suburb/City Per Capita Taxes

Ratio of 1970 suburban tax revenues per capita to 1970 central city tax revenues per capita ($\times 100$).

^a School segregation indices were made available by Karl and Alma Taeuber.

^b The racial disturbance data were made available by Seymour Spilerman.

Source: Advisory Commission on Intergovernmental Relations, 1973: Appendix B.

Suburb/City Per Capita Educational Expenditures
Ratio of 1970 suburban educational expenditures per capita to 1970 central city educational expenditures per capita ($\times 100$).

Source: Advisory Commission of Intergovernmental Relations, 1973: Appendix B.

City Crime Rate

Number of serious crimes reported in 1970 per 1000 central city population, 1970. Serious crimes include murder, rape, robbery, aggravated assault, burglary, larceny, and auto theft.

Source: U.S. Bureau of the Census, 1973b.

City-Suburb Commuters

Percent of 1970 central city residents reporting a place of work, that report a suburban workplace.

Source: U.S. Bureau of the Census, 1973c.

Factors Related to Population Structure

Postwar Suburban Development

Percent of 1970 suburban year-round units in structures built since 1950.

Source: U.S. Bureau of the Census, 1973b.

Percent City Owners

Percent of 1970 nonblack-occupied dwelling units in the central city which are owner occupied.

Source: U.S. Bureau of the Census, 1971.

City Age Distribution

Percent of the 1970 nonblack central city population aged five and over which was in the 20-29 year old age group in 1965.

Source: U.S. Bureau of the Census, 1973a.

APPENDIX C

LIST OF STANDARD METROPOLITAN STATISTICAL
AREAS INCLUDED IN ANALYSIS

New York City, N.Y.	Portland, Ore.-Wash.
Chicago, Ill.	Phoenix, Ariz.
Philadelphia, Penn.-N. J.	Columbus, Ohio
Detroit, Mich.	Rochester, N. Y.
Boston, Mass.	Dayton, Ohio
Pittsburgh, Penn.	Louisville, Ky-Ind.
St. Louis, Mo.-Ill.	Sacramento, Cal.
Baltimore, Md.	Memphis, Tenn.-Ark.
Cleveland, Ohio	Fort Worth, Tex.
Houston, Tex.	Birmingham, Ala.
Newark, N. J.	Toledo, Ohio-Mich.
Dallas, Tex.	Akron, Ohio
Milwaukee, Wis.	Hartford, Conn.
Atlanta, Ga.	Oklahoma City, Okla.
Cincinnati, Ohio-Ky-Ind.	Syracuse, N. Y.
Buffalo, N. Y.	Jersey City, N. J.
Denver, Col.	Omaha, Neb.-Ia.
Indianapolis, Ind.	Grand Rapids, Mich.
San Jose, Cal.	Richmond, Va.
New Orleans, La.

MEAD VS. BLUMER: THE DIVERGENT METHODOLOGICAL PERSPECTIVES OF SOCIAL BEHAVIORISM AND SYMBOLIC INTERACTIONISM*

CLARK MCPHAIL AND CYNTHIA REXROAT

University of Illinois

American Sociological Review 1979, Vol. 44 (June):449-467

An examination of the methodological perspectives of Mead and Blumer establishes considerable divergence in emphasis and consequence. Their diverse epistemologies rest upon equally diverse ontological assumptions. Blumer's naturalistic inquiry neither compliments Mead's methodological perspective nor facilitates the examination of Mead's theoretical ideas. Several experimental studies of "taking the attitude of other" are discussed, one by Mead's student Leonard S. Cottrell, which are consistent with Mead's methodological perspective. That perspective is equally applicable when exploratory-descriptive research is required. Many problems of naturalistic methodology are avoided by recognizing the different domains of meaning for investigator and investigated, by reducing the scope of behavior to be examined, and by increasing control of the investigator's behavior regarding that which is examined. An illustrative study is discussed.

INTRODUCTION

Although Herbert Blumer (1936:518; 1937:153) coined the term *symbolic interaction*, George H. Mead is an assumed forefather of this school of sociological social psychology. It also is widely assumed, by critics (e.g., Huber, 1973a) and by proponents alike (e.g., Stone et al., 1974), that the theory and methodology of Blumer's symbolic interactionism is the contemporary extension and manifestation of "the Meadian tradition." Both assumptions are false. Lewis (1976) has documented the diverse philosophical origins of Blumer's symbolic interactionism and Mead's social behaviorism. Bales (1966), Stewart (1975), and Stryker (1977) have noted but a few of many theoretical differences. The primary objective of the

present paper is to demonstrate the divergent methodological perspectives of Mead and Blumer.

We proceed by comparing Mead's and Blumer's characterizations and analyses of scientific inquiry. Mead's emphasis on systematic observation and experimental investigation is quite different from Blumer's naturalistic methodology. We attribute the striking epistemological differences to their disparate ontological assumptions and the application of those assumptions. Further, Blumer's ontology contradicts a basic premise of the theoretical perspective his epistemology was developed to investigate. Naturalistic inquiry neither compliments nor extends Mead's methodological perspective, nor is Blumer's framework suited to the investigation and development of Mead's theoretical ideas.

A second objective is to advocate and illustrate the investigation of Mead's theoretical ideas in terms of the methodological perspective he set forth. We note several studies by sociologists and others which are consistent with Mead's methodological perspective and which refute the belief that his most important theoretical ideas are beyond the empirical pale.

A third objective is to discuss some implications of Mead's methodological per-

* Direct all communications to: Clark McPhail; Department of Sociology; University of Illinois; Urbana, IL 61801.

An earlier version of this paper was presented at the 1975 annual meeting of the Midwest Sociological Society, Chicago. Numerous colleagues have since commented on the paper and we are grateful for their interest and effort. We particularly thank Charles W. Tucker (1969) for raising the issue and for providing, along with Robert L. Stewart, informed and constructive criticism. Neither may agree with all we have written here. We also thank J. David Lewis and Richard L. Smith who joined us in a 1974 seminar at the University of Illinois and with whom we have learned much about Mead's written work.

spective for redressing the problems of naturalistic methodology. Particular attention is given to the different "domains of meaning" for investigators and investigated, and, to variations in the investigator's scope and control of inquiry in exploratory-descriptive and experimental research. Melbin's (1972) study of interpersonal behavior illustrates several advantages of the application of a Meadian behavioral perspective to exploratory-descriptive research.

THE EPISTEMOLOGICAL PERSPECTIVES

Mead's concern with scientific epistemology developed early and remained central throughout his scholarly career. He had published several articles (1894; [1900; 1906; 1917] 1964) by the time Blumer (1928) completed his doctoral dissertation on "Method in Social Psychology."¹ A number of Mead's additional articles, typescripts and lectures (e.g., [1927] 1964; 1936; 1938a; 1938b) were available prior to Blumer's (1969:1-2) assertion that he was compelled to develop a symbolic interaction methodology to deal "... explicitly with many crucial matters that were only implicit in the thought of Mead." It is not clear by what criteria Blumer made his judgment that Mead's methodological perspective was "implicit" in his written work.² Our comparison of their respective

epistemologies will establish that Mead's position is far more detailed and explicit than Blumer suggests. It is also quite different from the position Blumer felt compelled to develop.

We draw primarily upon Mead's articles (e.g., [1917] 1964), typescripts (e.g., 1938b), and stenographic lecture notes (e.g., 1936, vs. student lecture notes, e.g., 1934), and upon Blumer's principal methodological statement (1969) and related articles (e.g., [1931; 1940; 1954] 1969). We first compare and contrast their respective positions on the antecedents and the initiation of scientific inquiry, followed by their discussions of the development and examination of hypotheses, and, the consequences for scientific knowledge.³

Antecedents of Scientific Inquiry

Mead and Blumer recognized antecedent theories, premises or beliefs are necessary presuppositions for individual scientific experience and investigation. Their respective emphases, however, are quite different. Mead's (1934:7) social behaviorism was an attempt to explain individual conduct and experience in terms of the antecedent and ongoing organized conduct of the social group. Thus, in his view of scientific epistemology, "... individual experience presupposes the organized structure" ([1917] 1964:203). That structure is not acquired inductively but is taught through formal instruction or through reading the theories and findings of preceding scholars (1938a:50). According to Mead, modern science holds that all theories are provisional (1938a:56); that extant scientific laws or beliefs are benchmarks in terms of which discrepancies or exceptions are experienced by the individual scientist ([1917] 1964:207); that exceptions should not be ignored but

¹ With few exceptions (e.g., McKinney, 1954; 1955; Huber, 1973a; Lewis, 1976; Lewis and Smith, 1980) sociologists do not acknowledge and seem generally unaware of Mead's extensive writings on scientific inquiry or, for that matter, any of his ideas beyond those in *Mind, Self and Society* (Spreitzer and Reynolds, 1973). In response to McKinney's (1954) paper on "Methodological Convergence of Mead, Lundberg and Parsons," Lundberg (1954:183-4) wrote: "McKinney's discovery will doubtless be a great shock to those whose careers as sociological theorists rest upon hearsay and imagination rather than on a serious perusal of the texts in question."

² We do not know the extent to which Blumer scrutinized the full range of Mead's writings and lectures on scientific inquiry. Blumer's (1928) dissertation makes several references to Mead's ([1917] 1964) "Scientific Method and Individual Thinker," one of four articles on scientific inquiry Mead had written at the time. Blumer's subsequent writings cite Mead's ([1917] 1964) article on two occasions (Blumer, 1973:797; 1977:289) but make no

further references to Mead's additional articles, manuscripts, or lectures on science published after Mead's death (e.g., Mead, 1932; 1936; 1938a; 1938b).

³ The phases of scientific inquiry in terms of which Mead organized his own discussion are found in his "Logical Analysis of the Experimental Method" (1938b). Blumer's phases are found in his (1969) statement on "The Methodological Position of Symbolic Interactionism."

should be acknowledged and stated as contradictions to be explained ([1917] 1964:173); and, that theories and beliefs are sources of alternate hypotheses to address those contradictions (1938a:56).

Blumer concedes that study of the empirical world presupposes some prior scheme through which research scholars view the world. Such a scheme includes both theories and beliefs about the phenomena to be investigated (e.g., the three theoretical premises of Blumer's [1969:2] symbolic interactionism) as well as beliefs about the nature of the empirical world which, in turn, affect how investigation will occur (1969:36). Blumer's characterization and analysis of the role of antecedent theory is erratic. On the one hand he is less sanguine than Mead with the adequacy of existing behavioral scientific theories, laws and beliefs. Extant theories cannot provide benchmarks when the majority of theoretical concepts are too vague and ill-defined to be used in scientific inquiry ([1954] 1969:138). Blumer says these concepts, at best, may serve as "sensitizing concepts" in a preliminary exploration of the empirical world. This may result in the development of more "definitive concepts." Yet, on the other hand, Blumer ([1940] 1969:181) warns of the "... risk and danger that the [theoretical] concept may coerce judgment and determine what is seen." He (1969:41) warns investigators to beware "imprisonment" by their antecedent theoretical schemes. It is not clear whether Blumer's warnings are superfluous, given his assessment of social science concepts, or if they are admonitions to avoid the development of definitive but coercive concepts.

Initiating Inquiry

Mead, and initially Blumer, construed the initiation of scientific inquiry as a matter of problem solution. Blumer's position has shifted across time and has never been as explicit or complete as Mead's analysis.

Mead (1938b:82) defines a problem as "the checking or inhibition of some more or less habitual form of conduct, way of thinking or feeling." Some aspect of the

scientist's system of beliefs or practices breaks down ([1917] 1964:198). This may involve an exception to or breakdown of a theory, law, hypothesis, unit of analysis, equation, or some piece of equipment. No area or phase of the scientist's activity or experience is immune (1936:264-5).⁴ Whereas the routine and ordinary escapes attention and scrutiny, the exceptional and extraordinary captures the attention of the puzzled investigator ([1917] 1964:190) and gives rise to such questions as: How can this activity be continued? What is the solution to this puzzle? How does this come about? Such questions provide occasions for creating hypotheses whose empirical investigation may reconstruct the empirical world and thereby modify or supplant existing laws, theories or beliefs.⁵ Such creative occasions distinguish the experimental method of modern science ([1917] 1964:189; 1936:264-6).

Blumer's ([1931] 1969) early writing construed problems as "puzzling perceptual experiences," as "frustrated activity," or as "situations requiring solution or adjustment." But his more recent writings have reversed the problem-question sequence: scientific inquiry is said (1969:25) to begin by "asking questions of the empirical world and the conversion of those questions into problems."

While it may be argued that the sequence of problem and question is not crucial, it is clear that Mead and Blumer provide quite different analyses of what is required to prepare a problem for resolution. The scientist should (Mead, 1938b:82) "state the problem in terms of the conditions of its possible solution." Where a law, theory or belief has been found exceptionable, the problem should be so stated (1936:283). One should pro-

⁴ But Mead ([1917] 1964:200) cautions confusing the "scientific attitude of being ready to question anything with an attitude of being willing to question everything at once." Scientific inquiry would be impossible without some unquestioned and stable ground on which to stand, from which to judge some other activity problematic, or, upon which to construct a solution or redress of the problem.

⁵ Mead does not distinguish, as does Kuhn (1962), between the "puzzle-solving activities" of normal science, and the anomalies which are goads to scientific revolutions.

duce descriptions of as many instances of the problem as possible and thereby increase the facts known about the problem (1936:283-4). The greater one's familiarity with the phenomenon, the more likely one is to recognize the problematic features with which an adequate hypothesis must deal (1936:284). Notwithstanding the investigator's individual and private experience of the problem, it must eventually be rendered social; that is, the scientific existence of the problem depends on others' acceptance of the report of the person who initially experienced the exception or discrepancy ([1917] 1964:196). The investigator must provide the "circumstantial evidence" of the conditions of the exception such that others might have a similar experience and provide a report similar to that of the initial investigator. And this should not depend upon personal whim or fancy ([1917] 1964:196-7):

In other words, those individuals who corroborate the facts are made in spite of themselves, experiencers of the same facts. The perfection of this evidence is attained when the fact can happen to others and the observer simply details the conditions under which he made the observation, which can be then so perfectly reproduced that others may repeat the exceptional experience.

Blumer (1969:25-6) has appropriately observed that most scientists have little familiarity at the outset of their inquiry with that portion of the empirical world in which their problem lies. Blumer concedes no substitute for getting close to this empirical world to gain that familiarity (1969:27). He has proposed a two-stage procedure for accomplishing such an examination. *Exploration* or description is the first stage and the objective is to:

... enable the scholar to ... talk from fact and not from speculation ... so that he knows that the questions he asks of the empirical area are meaningful and relevant to it, that the problem he poses is not artificial, that the kinds of data he seeks are significant in terms of the empirical world, and that the leads he follows are faithful to its nature. (1969:42)

We noted Blumer's disdain for the majority of social science concepts and the "sensitizing" role he assigns them in the preliminary exploration phase of in-

quiry. These may be refined in the second stage of inquiry—*inspection*—where the investigator *discovers* the analytic elements or conceptual categories with which she or he will subsequently work. Again, Blumer's treatment of the nature of such analytic units has shifted across time. In an early paper he wrote that the character of an observed act is "lodged there through a process of inference" ([1940] 1969:179). In his methodological position statement, however, he argued (1969:45) that inspection and pursuant concept development do not involve "giving a nature" to the analytic element; rather, it is a matter of discovering or identifying "the nature of the analytic element by an intense scrutiny of its instances in the empirical world" (1969:45). Blumer's position corresponds to the Aristotelian conception of observation of which Mead ([1917] 1964:183-4) was so critical. For Mead, modern science emphasizes the controlled perception of observed fact and the controlled reconstruction of a perceived world. Aristotelian observation emphasized the insight with which an observer could recognize the nature of the object, analyze that into essences and formulate those into a definition of the object. Such an emphasis precludes the reconstruction of observed fact and the expansion of knowledge. In short, Blumer and Mead agree the solution of a problem cannot be achieved until one is first familiar with the problem to be resolved. But Mead, unlike Blumer, requires and discusses procedures for the controlled perception of observed facts and for establishing scientific problems as social objects.⁶

Hypotheses

Mead ([1917] 1964:198) treats the hypothesis as a tentative solution to a prob-

⁶ Blumer neither is unaware of these issues nor of crude procedures with which they could be addressed. But he has given them such scant attention (e.g., 1928:410; [1940] 1969:179), or has discussed them in such obscure locations (1969:45, fn.) that we can only conclude he considers them unimportant. This is a point on which Blumer's critics have made properly sharp attacks (cf. Huber, 1973a; and, particularly, 1973b: "But Who Will Scrutinize the Scrutinizers?").

lem, an "escape from the exception." It is an answer to the question: How did this exception come about (1936:284)? The hypothesis is characterized as "some possible representation, restatement or reconstruction of the situation in which the data or facts will no longer inhibit action, thought or feeling" (1938b:82).⁷ Mead recognized the individual as the source of those exceptional experiences which establish problems as well as the source of hypothesized solutions to those problems ([1917] 1964:207). But he did not construe hypotheses as individualistic, particularistic or atheoretical exercises. Theories are sources from which hypotheses (1938a:56) develop, and such ideas (1938b:82) represent efforts to test competing theories or portions thereof (1938a:84-6). Although one after another hypothesis may prove faulty, be abandoned, and others may be required, none can be considered a tenable research instrument unless cast in universal form ([1917] 1964:198): "No one would waste time with a hypothesis which confessedly was not applicable to all instances of the problem." Finally, Mead (e.g., [1917] 1964:193) consistently suggested that hypotheses be subject to empirical test.

Blumer avoids the term *hypothesis*. In the exploration stage Blumer's ([1931] 1969:166) investigator works with a theoretically primitive sensitizing concept which represents a "mode of attack or a plan of approach to the situation . . . requiring solution or adjustment." The inspection stage of inquiry may refine that concept and establish an analytic component. The next task is to isolate relationships between analytic components. This "presumes the existence of a meaningful connection between components in the empirical world" (1969:46, Blumer's emphasis). The connection, like its analytic components, is not assigned or hypothesized. It is discovered, " . . . pinned down and tested by careful flexible scrutiny of its empirical instances"

(1969:46). Whereas Mead treats hypotheses as the beginning of an empirical resolution of the problem of inquiry, Blumer seems to treat the discovery of a relationship between analytic components as the termination of the empirical resolution. Whereas Mead's treatment of hypotheses is theoretically grounded, though not formally deductive,⁸ Blumer's treatment is virtually atheoretical, inductive empiricism.

Examining Hypotheses

Mead's analysis of scientific inquiry discusses the examination of hypotheses by means of experimental and nonexperimental observation as well as with "thought experiments."⁹ The experimental method "undertakes to tell us what we may expect to happen when we act in such and such a fashion" ([1917] 1964:210) under "specific, exact and hence formally universal" conditions the investigator has identified or constructed (1938b:82).¹⁰ Some critics (e.g., Huber, 1973a:278) have charged that Mead treats the experimental method as merely an extension of the everyday processes of trial-and-error problem solution employed by all higher primates. Such criticism ignores Mead's

⁸ Mead (1938b:83) recognized the inductive/deductive strategy is never clear-cut: "Indeed, all formulations of problems are deductive, whether we undertake their solution or not, but [in the impractical situation requiring 'thought experiments'] . . . the method of approach seems [necessarily] to be entirely deductive."

⁹ Mead recognized that experimental tests of hypotheses are not always practical or possible in all fields of scholarship. The problem of inquiry may be considered inevitable or insoluble. Or the community may be afraid to have situations manipulated because of the social reorganization which might occur (1938b:83). In such situations the "mental testing of the hypothesis" (1938b:82), or the "thought experiment," provides a procedure for the logical examination of relational statements in the form of the syllogism, testing past experience to ascertain the consequence of taking future hypothetical action (1938a:85; cf. Kuhn's discussion, 1962:88). It can be argued that correlation studies are of this sort.

¹⁰ Mead ([1906] 1964) considered experimental analysis to be the method of modern science. He did not construe experiments as techniques of data collection and analysis but as requirements and procedures for generating knowledge. See his (1938) "Logical Analysis of the Experimental Method."

⁷ Where the problem is a factual exception to some hypothesis, law or theory, the superceding hypothesis must account for the exceptional facts, the facts accounted for by the superceded hypothesis, and, the superceded hypothesis itself (1938a:39).

(1938b:82) emphasis on "the careful exactness with which the problem is defined, the data gathered, and the experiment carried out" by the investigator. Mead (1932:101; 1936:406, 415; 1938a:40) also stressed the investigator's obligation to specify the criteria and procedures enabling others to replicate and reject or corroborate the investigator's actions and reported consequences.

Blumer (1969:28-31) rejects "the four customary means" of empirically validating relationships between analytic components. "Hypothesis testing" is rejected (1969:29-30) because it seldom "genuinely epitomizes the model or theory from which it is deduced," because it neglects the search for negative cases, and because it is limited to the particular empirical situation circumscribed by the hypothesis rather than extending to other relevant empirical situations. Blumer (1969:28-9) rejects "adherence to scientific protocol" because it provides no guarantee that the investigator's premises, problems, data, relationships, concepts and interpretations are "sustained by the nature of the empirical world." Similarly, Blumer (1969:30-1) rejects "operational procedures" because they are "regularized" and have too limited a range of empirical referents to allow true validation. The consequence of this is that Blumer (1969:29) also rejects "replication studies" because they beg the question if the primary study was without valid grounding in the empirical world.

In short, Blumer rejects all that Mead requires. Blumer neither discusses or requires procedures for corroborating the problem solution an individual investigator may claim to have achieved. Instead he argues that exploration and inspection alone are necessary to ascertain relationships between analytic components in the empirical world (1969:46):

They comprise what is sometimes spoken of as "naturalistic" investigation—investigation that is directed to a given empirical world in its natural, ongoing character instead of to a simulation of such a world, or to an abstraction from it (as in the case of laboratory experimentation).

To the contrary, Mead (1938a:35) chastizes critics of experimental research.

It is a mistake to emphasize the artificiality of the experimental apparatus and technique of the psychological laboratory. As in the case of the laboratories of the physical sciences, the building of its apparatus and its techniques is but rendering specific, exact and hence formally universal the instruments and behavior of untechnical conduct.

Experiments rest upon the systematic observation of the consequences of the investigator's activities for the phenomena under study ([1917] 1964:210). Mead (1934:2) characterized his social behaviorism as "an approach to the study of the experience of the individual from the point of view of his conduct, particularly, but not exclusively, the conduct as it is observable by others." He did not construe observation as a matter of recording "the natural ongoing character" of things. Observation ". . . is not simply the opening of one's eyes and seeing things as the images happen to fall on the retina" (1938a:283), nor is it merely "opening one's ears and listening to what may occur" (1936:281). Rather, observation is guided by the problems or interests of the investigator ([1917] 1964:192) who is actively and selectively "discriminating" (1938a:350) what is to be observed.¹¹

Just as Mead (1938a:40) stressed others' corroboration of the problem, so too must others verify the investigator's report of the consequences of his or her hypothesis: "It is in the mouths of at least two witnesses that [these observation reports] must be confirmed." Science is social behavior! Others should not be expected to accept the new hypothesis as a matter of blind faith nor as a "deduction from accepted impersonal premises" (1938a:40). The investigator must specify the conditions to be met and the actions to be taken such that others, through their conduct, can experience, must observe, can confirm or reject the reported observations of the investigator (1936:406, 415). "The reality of this experience of his, and of others carrying out the experiment, is the

¹¹ "What we call 'discrimination' [is] the pointing out of things and the analysis in this pointing. This is a process of labeling the elements so that you can refer to each under its proper tag, whether that tag is a pointing of the finger, a vocal gesture, or a written word" (Mead, 1938a:350).

cornerstone of experimental science" (1932:101).

The Consequences of Scientific Inquiry

Blumer's treatment of the theoretical consequences of inquiry is as equivocal as his discussion of the theoretical antecedents. On the one hand he has argued ([1954] 1969:148) that every object of empirical consideration has a distinctive character. This would seem to preclude the development of abstract concepts and universal statements of relationship between such concepts (cf. 1969:45; but also see [1954] 1969:140-1). Nonetheless, Blumer (1969:26) calls for the scientist to move beyond the empirical findings from a problem's investigation to some transcending theory or outside conceptual scheme. Once relationships between analytic components have been discovered, Blumer's (1969:48) investigator is directed to formulate propositions, weave these into a theoretical scheme, and submit all to test by renewed examination of the empirical world. Perhaps Blumer is simply calling for theory development by analytic induction. The empirical test of theoretical generalizations, however, seems precluded by his rejection of scientific protocol, operational procedures, hypothesis testing or replication studies. Ostensibly, exploration and inspection can suffice (1969:46).

Mead (1936:285) made explicit and consistent references to the consequences of hypothesis testing for the body of theory within which the investigator has worked.

You are undertaking to set up another law in place of the one which has been overthrown. The new law is tentatively set up as a hypothesis. You test it. When you have tested it, it becomes a working hypothesis. And if others test it and it works, it becomes an accepted theory. But, although it is an accepted theory, it is still subject to some other chance exception.

The Epistemologies Reviewed

Blumer's characterization of and recipe for naturalistic inquiry neither extends nor explicates Mead's analysis of scientific inquiry. Mead stressed antecedent theory

as a source of benchmarks against which exceptions are noted in individual experience as problems which occasion inquiry and solution. Such individual experiences presume the organized structure of antecedent theory. Blumer vacillates between orienting and confining consequences of existing theory but generally disparages the quality of that theory and opts for an ad hoc approach.

For both Mead and Blumer the problematic exception requires careful observation and description to establish or grasp those features of the phenomenon with which the investigator's proposed solution must deal. Thereafter, Mead's and Blumer's emphases increasingly diverge. Mead treated the hypothesis as an escape from the problematic situation, and, hypotheses require observation, experimental or logical test by the investigator and then by others. Blumer eschews the term *hypothesis*, not to mention the specification of criteria and procedures by which hypotheses could be tested. Blumer emphasizes the discovery of analytic elements and relationships among them in a two-stage process of naturalistic inquiry. His concern is with encompassing observations that preserve the natural character of the real, ongoing empirical world. Mead stresses "the controlled perception of observed facts," and repeatedly emphasizes the necessity of corroborated factual statements of the problem as well as corroborated observations of the hypothesized resolution of that problem. Blumer ignores corroboration.

Blumer's epistemological perspective lends itself to repeatedly starting inquiry anew (others' theoretical schemes are inadequate guidelines) or of retracing the same ground (by renewed empirical examination of the relationships one uncovers and weaves into a theoretical scheme). There is no sense of "normal science" (cf. Kuhn, 1962) in which knowledge is corroborated and accumulated across investigators. Conversely, Mead's perspective emphasizes the corroboration of individual experience and the social accumulation of knowledge which this allows; he recognizes that (1936:286): "No statement that science makes is final There is

always some possible reconstruction that can take the place of it The law is dead! Long live the law!"

Discussion

One explanation for the divergence of Mead's and Blumer's methodological perspectives is that Mead's views are restricted to the physical and biological sciences. Some symbolic interactionists (e.g., Meltzer [1964] 1972:21) have even asserted that Mead made "no specific recommendations as to the techniques appropriate to the study of human behavior." Such assertions may stem from a lack of familiarity with Mead's extensive writings on scientific inquiry or from a rejection of their applicability to human behavior. Blumer has rejected the use of established scientific protocol (1969:28-9) and has cautioned against the emulation of physical science (1969:34) in the study of human behavior. The apparent reservation is that scientific protocol prevents the investigation of human actors' meanings and interpretations whereas proper inquiry (Blumer, 1966:542; 1969:56) would have the investigator "take the attitude" of the investigated and thereby similarly perceive and interpret the latter's situation and behavior. Such reservations may have led to the erroneous conclusion (Blumer, 1969:1) that a methodology for the study of human behavior was at best implicit in Mead's writings, thereby compelling Blumer to develop one of his own.

We reject Blumer's conclusion and the assumptions on which it rests. First, Mead construed scientific inquiry as the explicit and formal extension of the everyday processes of intelligent problem solution to all areas of human inquiry, including those of human conduct and experience (cf. Mead [1906] 1964:61; [1917] 1964; [1923] 1964:246-65; 1936). Second, Mead's (1934:2) social behaviorism is an approach to human experience through behavior, and not the other way around!¹² Third, those

sacrosanct human qualities some symbolic interactionists have held above and beyond the scrutiny of scientific inquiry, Mead simply construed as behaviors in which humans engage. Thus, "the meaning of the object is derived entirely from our reaction upon it, or, in other words, our use of it" ([1900] 1964:8). "Interpretation . . . is not basically a process going on in the mind as such, or one necessarily involving a mind; it is an external, overt, physical or physiological process . . ." (1934:48-9). Similarly, "taking the attitude of the other" is construed ([1912] 1964:140; [1913] 1964:145-6; [1922] 1964:243; [1924-25] 1964:380-1; [1927] 1964:312) as a behavioral or physiological process in which the individual responds to his/her own gestures (or to other's gestures) as other responds. In short, no unique methodology is required to study human behavior, at least not in terms of Mead's theoretical perspective.

A second explanation for the divergent epistemologies is that Blumer's perspective is limited to the exploratory-descriptive research which must precede the hypothesis testing and experimental work with which Mead was concerned. Although Blumer (1969:46) explicitly disavows such limitations on his perspective, this interpretation has mixed merit. It is the case that social and behavioral scientists too frequently proceed to test hypotheses before they have sufficient descriptive familiarity with phenomena they seek and claim to explain.¹³ Unfortunately, there are too many flaws in Blumer's methodological perspective to facilitate the quality of exploratory observation and description on which sub-

"It is much safer . . . to come back to the conduct of the individual if you are going to study him than to come back to something he reports to you by means of introspection."

¹³ Blumer's pleas for investigating "the real empirical world" must be placed in the context of his career which paralleled the attrition of direct sociological research contact with the phenomena of interest. Detailed case studies increasingly were replaced by survey research, magnetic tapes and secondary analyses. Blumer may have been incensed at the increasing number of sociological pathologists who never observe or speak with a live human subject but merely scrutinize residual data in *computer*.

¹² Most symbolic interactionists, following Blumer, have twisted Mead back to front on this point. They have insisted on an introspective approach which Mead (1936:400) explicitly rejected:

sequent investigations must build. We attribute those flaws to the ontological assumptions Blumer makes about what is to be observed and about the observation process itself. Our discussion of some alternatives to naturalistic observation and description must await consideration of these basic ontological issues.

A third explanation attributes Mead's and Blumer's epistemological differences to their ontological assumptions and the uses to which those assumptions are put. All recipes for generating knowledge rest upon assumptions about reality. Both Mead (e.g., 1936; 1938a:276-300) and Blumer (e.g., 1969:36, 60) discuss the ontological assumptions of scientific epistemology. The closing injunction of Blumer's (1969:60) major methodological essay reiterates the importance in which he held such assumptions: "Respect the nature of the empirical world and organize a methodological stance to reflect that respect." We have reviewed Mead's and Blumer's epistemological stances. We turn now to an examination of the ontological assumptions on which those diverse stances have been organized.

ONTOLOGICAL ASSUMPTIONS AND APPLICATIONS

Mead (1936) traces the development of modern science and the accompanying rejection of realism and idealism at the turn of the century. He advances pragmatism as an alternative to those ontological positions and as the logical generalization of scientific methodology and behavioral psychology. Mead (1932:275) concedes we might imagine a disorderly world but denies we can imagine a world that is not there. Reality is a presupposition of all scientific inquiry, indeed of all thinking (1938a:275). But science is not concerned with the nature of reality (1936:275); rather, science is concerned with "ordering the events it observes." Investigators' responses impose order on observed events. Those events are not solipsistic inventions. The manipulatory phase of the act meets a resistance which answers to the preceding perceptual phase of that act (1938a:104-5). While the scientist assumes the reality of perceptions

(1932:140), of recording instruments (1932:150), and of the events predicted by hypotheses (1932:140), "[c]ontrolled sensuous experience is the essential basis of all our science" ([1903] 1964:34). It is the social and behavioral control of experience that characterizes the ontological assumptions of Mead's pragmatism, and provides the basis for his view of scientific inquiry.

Blumer (1969; 1977) claims the ontological position of pragmatism, but Lewis (1976; 1977) demonstrates that Blumer's version is derived from James and Dewey and is quite different from the pragmatism of Peirce and Mead. Blumer (1977), of course, vehemently denies any divergence from Mead. But our examination of his writings suggests he waffles amongst the ontological assumptions of both realism and idealism. On the one hand (1969:46) his naturalistic inquiry is concerned with "the natural, ongoing character" of the empirical world which can "talk back . . . challenging and resisting . . . not bending to our images or conceptions of it" (1969:22). On the other hand he has written that the world of reality depends on how it is perceived (1977:287) and exists only in human experience (1969:22). Blumer's vacillation beds him down with both idealists and realists. He simply never adopts the social behaviorist perspective by which Mead's pragmatism transcends the idealist-realist gap.

Mead's ontological assumptions logically extend to his characterization of meaning as response ([1900] 1964:8), and of shared meaning (1934:78), scientific universals (1938a:275) or laws (1936:285) as convergent responses. It is never clear how Blumer defines meaning or shared meaning.¹⁴ It is clear he fails to do so in terms of behavior or convergent behaviors.

¹⁴ Blumer "explains" that "the meaning of a thing for a person grows out of the ways in which other persons act toward a person with regard to the thing" but he does not provide a definition of meaning, let alone a behavioral definition. Similarly, he "explains" that shared meaning "arises in the process of interaction between people," but he does not define it nor tell us how to recognize it when it occurs. Thus, in spite of the significance of meaning to Blumer's theory of human behavior, he provides neither a definitive nor a sensitizing conceptualization to assist in its empirical description and analysis.

He clings to reality with one hand and hails the subjective experience of the individual with the other. For example, his recent discussion of Mead's ontological position properly claims the meaning of "a reality that is 'out there'" is contingent upon the perspective of the perceiver (1977:287). But Blumer predictably neglects Mead's social and behavioral treatment of perspectives. He incorrectly attributes to Mead the notion that (1977:287) "because the perspective outlines or indicates something 'out there,' the perspective has an objective character." To the contrary, Mead's discussion of the "objective reality of perspectives" ([1927] 1964:315-6, 318) emphasized "the relation of a consentient set [conjoined judgments] to a percipient event [something that can be perceived]." Objectivity of perspectives is not contingent upon a perceptible event, as Blumer suggests, but upon a convergent response to such an event!

Blumer (1977:289) insists on characterizing Mead's treatment of scientific inquiry as "an individual act." This is an error. We recognize that Mead's ([1917] 1964:196) essay on "Scientific Method and Individual Thinker" lauds individual experience as the growing point of science, both in the recognition of exceptional facts which fracture extant theory, and in the generation of alternative hypotheses to transcend the exception. But Blumer fails to recognize Mead's ([1917] 1964:196) requirements that exceptional facts and their circumstances be so described by the initial investigator that others will experience the facts, and, that the investigator's working hypothesis be set forth for and corroborated by others. Just as the initiation of individual scientific inquiry "presupposes an organized structure" ([1917] 1964:203), the continuity of scientific inquiry requires that individual experience be rendered social. Any object remains subjective so long as it is indicated by an individual solely to him or herself ([1922] 1964:242). It is the "coincidence of the perspective of the individual with the perspective of others" which constitutes the objectivity of the perspective ([1927] 1964:318). And, "the character of [scientific universals] arise[s]

out of the social attitude of the individual [investigator] toward the world" (1938a:275), and not out of the nature of the world.¹⁵ Given the concern of science (1936:275) with "ordering the events it observes," the investigator must direct others to respond as he or she has responded. Mead proposed the significant symbol as the mechanism for accomplishing these convergent responses, coincident perspectives, and scientific universals.

Mead ([1927] 1964:312) defined the significant symbol as "a gesture [which] arouses the same response in the individual who makes it that it arouses in others." The vocal gesture is preeminent because of the simultaneity with which speaker and hearer perceive the gesture; but similar consequences can occur with gestures we can see or feel ([1922] 1964:243). "We hear what we say; if we are talking with our fingers we see what we are saying; if with the attitudes of the body, we feel what we are saying" (1936:379). For social intercourse in general, and science in particular, "the individual can indicate to others and to himself the perceptual things that can be seized and manipulated and combined" ([1927] 1964:314-5). Objects can be established ("pointed out") for others as they have been established by and for the individual (1936:287), and the individual can direct others to respond to the objects as the individual has responded or is responding (1936:380). These directions, and the convergent responses they produce, are the social behavioral mechanisms of the ontological assumptions upon which Mead's methodological perspective is constructed.

Blumer attends to neither the convergent responses which constitute the objective reality of perspectives nor to the significant symbols responsible for those convergent responses. Mead's (1936:275)

¹⁵ In the usage of his times, Mead ([1924-25] 1964:286-7) defined attitudes as vocal and non-vocal gestures: "stages in the act as they appear to others, [including] expressions of countenance, positions of the body, changes in breathing rhythms, outward evidence of circulatory changes, and vocal sounds." Thus, social attitudes are convergent behavioral responses by the investigator and other(s).

ontological perspective dismisses any concern with the "nature" of observed events. Rather, the investigator is required to provide directions which will occasion the convergent responses which order observed events. Blumer's ontological perspective, if anything, requires the opposite. He directs investigators (1969:39, 45) *not to assign but to discover the nature of their concepts*. They are directed *not to impose relationships* upon their analytic components *but to discover them* through intense scrutiny of the empirical world, presuming "the existence of a meaningful connection between the components in the empirical world" (1969:46).¹⁶ Blumer (1969:29) insists that ordinary scientific protocol will not suffice because its constituent elements might not be "sustained by the nature of the empirical world." Rather, a naturalistic investigation is addressed to the "natural, ongoing character" of the empirical world (1969:46), "lifting the veils that obscure or hide what is going on" (1969:39), and thereby digging out and discovering "the nature of the empirical world" (1969:48). The consistent respect in which Blumer holds "the nature of the empirical world," and his lack of attention to investigators' convergent responses and the instructions which produce them, give us the ontological assumptions upon which his naturalistic methodology is constructed.

Blumer's Ontological Paradox

Symbolic interactionists traditionally have rejected the notion that inherent meanings or intrinsic stimuli control human behavior. Blumer has held that human actors do not merely respond to surrounding stimuli but, rather, forge and direct their respective lines of action. "The position of symbolic interactionism is that the social action of the actor is

constructed by him" (1969:23). The ontological assumption is clear: *human actors impose meaning and order upon their own and others' activities*. Blumer sets this assumption aside, however, when describing and prescribing the investigation of human behavior. "For symbolic interactionism the nature of the empirical world is to be discovered, to be dug out by a direct, careful and probing examination of that world" (1969:48, our emphasis). Blumer never characterizes investigators as constructing the meaning or forging the order of the actions they investigate, nor does he instruct them to do so. The antithetical ontological assumption is clear: *human investigators reveal the meaning and order in the actions of others* by merely lifting the obscuring veils.

Blumer applies one set of ontological assumptions to the phenomena under investigation and another to the investigation of those phenomena. The paradox is that Blumer's methodological perspective abandons one of the basic premises of the theoretical perspective it was designed to investigate. If meaning and order are constructed and assigned, naturalistic inquiry is antithetical to social behaviorism and to symbolic interactionism as well.

Review and Implications

Mead rejects realism and idealism and consistently assumes a pragmatist position: reality is presumed, but science orders observed events through convergent responses which establish objective facts for science and shared meaning in other arenas of human conduct. It is upon these assumptions that Mead's methodological perspective and his social behaviorist theoretical perspective are constructed.

Blumer vacillates between idealism and realism. The pragmatist stance he claims bears no resemblance to Mead's position. Moreover, Blumer's naturalistic methodology is inconsistent with a basic premise of Blumer's symbolic interactionist theory. The order Blumer's methodology seeks to discover in the world flatly contradicts his theoretical claim that human actors impose order on that world. Blumer (1969:60) may have organized his epistemological stance to reflect what he as-

¹⁶ Some contemporary social psychologists, like Mead a half-century earlier, recognize that "laws and theories are not physical things which lie hidden beneath the bushes waiting for us to serendipitously trip over them. . . . They are man-made abstractions . . ." (Schlenker, 1973:12). Similarly, Zajonc (1972:2) observes that "order is not a feature of the universe and of nature but of the scientist's conceptions of the universe and of nature."

sumes to be the nature of the empirical world, but neither his assumptions nor his stance bear remote resemblance to those of the putative forefather of symbolic interactionism, George Herbert Mead.

A wide range of students of human behavior continue to pay homage to Mead's seminal theoretical ideas. But they also typically despair the systematic empirical investigation of those ideas. We attribute that despair to the confusion of Mead's ideas with the theory and methodology of symbolic interactionism. For example, Shaver (1974) writes that

. . . G. H. Mead is mentioned with reverence by several [contemporary European social psychologists] but no improvements in the methods of . . . symbolic interactionists are proposed. Mead's ideas have always been attractive but have yet to inspire novel methods or empirical findings.

It is true that Blumer studied with Mead and has assumed the role of sociological interpreter for Mead's ideas. But our review suggests that Blumer's symbolic interactionist methodology is, at best, an improvident vehicle for the systematic investigation of Mead's social behaviorist ideas and may, in fact, have thwarted such an investigation. Alternatively, Mead's ideas can be investigated in terms of his own methodological perspective.

INVESTIGATING MEAD'S IDEAS ON HIS OWN TERMS

How do two or more persons get their acts together in concert? (Mead, 1936:360-85). Mead (1936:377) put forth as "the principle of organization" the use of a gesture by the individual which calls out the same response in the user as it calls out in the other(s) to whom it is addressed. Such a response may be common to "the generalized other" within the language community of which the individual and others are a part. Convergent responses coestablish objects and codirect additional behavior toward, away from, and with respect to those objects (1936:378). Mead ([1927] 1964:312) used the term *significant symbols* to refer to the vocal or nonvocal gestures which elicit such common responses. The common responses themselves—that is, responding

to a gesture as another responds—Mead called "taking the attitude of the other" ([1912] 1964:140; [1913] 1964:145-6; [1922] 1964:243; [1924-25] 1964:380-1; [1927] 1964:312). The individual may respond to his or her own gesture as other responds or may respond to other's gesture as other responds.

"Taking the attitude of the other" is an article of faith long proclaimed by social behaviorists and symbolic interactionists. It has only recently been submitted to empirical examination. It is comparatively easy to observe and judge whether one person's ongoing behavior is altered corresponding to the vocal or nonvocal directions given by another.¹⁷ It is more difficult to observe the reflexive responses of an individual to his or her own directions. It is much more difficult to investigate reflexive responses when the vocal directions are covert. Three investigations have addressed these problems.

The nonvocal gesture of a mother extending a spoon of food toward an infant's mouth is frequently accompanied or followed by the mother opening her own mouth.¹⁸ In Mead's terms this constitutes "taking the attitude of the other" toward one's own nonvocal gesture. O'Toole and Dubin (1968) systematically observed 26 mothers spoon feeding their infants. They recorded 1,013 feeding acts (\bar{x} = 39 per feeding session), the direction of the baby's gaze orientation at the beginning of each act, and, whether the mother opened her mouth before or after the baby's mouth opened. Two of the mothers never opened their mouths at all and no mother opened her mouth on every feeding act. But mothers were observed to open their mouths in 59% of all their feeding acts.¹⁹

¹⁷ The exemplary research, consistent with Mead's theoretical and methodological perspective, is Rigney's (1972) behavioral examination of compliance.

¹⁸ This is not limited to the interaction of mothers and infants. Adult male and female nurses are observed to engage in the same reflexive responses when spoon feeding patients of all ages and sexes.

¹⁹ Four opened in 75-99%; thirteen in 50-74%; five in 25-49%; and two in 1-24% of all their feeding acts. Mothers were four times more likely to open their mouths following the baby's mouth opening whether or not the baby was looking in the direction of mother.

The majority engaged in reflexive responses to their own nonvocal gestures.

Vocal gestures are hypothesized (Mead, [1922] 1964:244-5) to have the same effect: "In giving directions, we give the direction to ourselves at the same time that we give it to another. We assume also his attitude [gesture] of response to our request" Smith (1971) coded videotape records of the vocal and manual gestures of 42 subjects as they gave overt vocal directions to another person (an accomplice of the experimenter). Subjects differed other to assume a sequence of six different hand positions (e.g., upturned, open palms; interlaced fingers). Smith judged that subjects engaged in manual gestures corresponding to their vocal directions to other from 41% (upturned, open palms) to 81% of the time (interlaced fingers) across the six different hand positions. The majority (\bar{x} = 60%) of persons engaged in reflexive responses corresponding to their own vocal gestures to other.

We do not readily and easily observe all human beings engaging in reflexive responses to their own vocal and nonvocal gestures. Such responses may be truncated or even covert. O'Toole and Dubin (1968) and Smith (1971) comment that additional reflexive responses might have been recorded with more sensitive measures of muscle tension. A colleague of Mead at the University of Chicago, Edmund Jacobson (1931), succeeded in producing electromyographic measurements of Ss' muscle movements corresponding to the actions they were asked to imagine performing (cf. Jacobson, 1973).

Mead's theoretical perspective suggests that when an individual observes or imagines another's performance of some behavior, the individual provides a running description of that behavior to him or herself. Such a description should call forth a rudimentary response similar to the behavior under observation or imagination. O'Toole and Dubin (1968) told Ss to observe carefully a series of situations so they could later describe them as accurately as possible. The S stood facing in the direction of an actor standing at the opposite end of the room. The actor leaned forward in the direction of an ob-

ject centered out-of-reach on a large square table. The leaning movement was repeated from all four sides of the table. Ss' lateral, rearward and forward body sway was measured. The Meadian hypothesis predicts forward sway by Ss regardless of the table location of the actor. O'Toole and Dubin report an average of 55% of the subjects did sway forward in all four of the actor's table locations. Mead's hypothesis is supported.²⁰

Leonard S. Cottrell, a student in Mead's 1930 Advanced Social Psychology course, examined a similar phenomenon with more sensitive measures of covert reflexive response. Cottrell (1971) directed Ss to observe and judge two activities performed by an experimenter. S and E were seated and facing across a small table with bared forearms resting on the table. S was told that E would squeeze a manometer bulb (with his right hand) with varying degrees of pressure and that S should observe each of 15 such squeeze trials, make a judgment by pressing a tension key with his own left forefinger to indicate hard, medium or light pressure.²¹ In the second part of the experiment S was asked to observe, to make and report judgments of "how hard" E clenched his jaw on 15 trials. For misdirection, Ss were told the experiment concerned electrical charges in the frontal area of the brain during observation and judgment tasks. Thus, an electrode was placed on the S's forehead along with "ground" electrodes in the right arm and cheek. In fact, the former electrode was the ground and the latter electrodes measured tension in the arm (flexor carpi radialis) muscle during hand grasping, and in the cheek (masseter) muscle during jaw clenching. Electrodes and tension key were fed to a Grass Electroencephalograph machine located in a separate room. This produced an elec-

²⁰ Average backward sway was \bar{x} = 18%; to the right, \bar{x} = 5%; to the left, \bar{x} = 2%; and, no sway averaged 20% across the four positions.

²¹ E held the bulb in his left hand, S pressed the key with his right forefinger, and the "ground" electrode was placed on S's left arm in the four cases where Ss were left handed. All Ss' tension key presses were calibrated prior to the first trial by having them practice giving what they considered several hard, medium and light presses.

tromyographic record of base level muscle tension prior to the beginning of the trials, and of increases and decreases in muscle tension level across trials.

Cottrell reports that 40 Ss' arm muscle tension levels significantly exceeded their base tension levels during the interval E was observed to squeeze the manometer bulb, but decreased significantly during the period following E's release of the bulb. Correspondingly, he reports that 40 Ss' masseter muscle tension levels significantly exceeded their base tension levels during the interval E was observed to clench his jaw but decreased significantly during the period following E's unclenching of his jaw (all differences, $p < .001$). The Meadian hypothesis receives further support.²²

These investigations of Mead's idea—"taking the attitude of other"—have been carried out by sociologists in a manner consistent with Mead's methodological perspective. The common denominator is an attempt to approach Mead's ideas behaviorally. Many symbolic interactionists have failed to recognize that Mead rejected Watson's behaviorism because of the limits which Watson, *not* Mead (1934:10), placed on such an approach.

... [I]t is not possible to deny the existence of mind or consciousness or mental phenomena, nor is it desirable to do so; but it is possible to account for them or deal with them in behavioristic terms which are precisely similar to those which Watson employs in dealing with nonmental phenomena.

Thus Mead set forth a social behavioral approach to society, self and mind which lends itself to investigations such as those summarized above.²³ Mead's perspective

is not limited, however, to experimental examination. His social behaviorist perspective can provide guiding theoretical and methodological assumptions for exploratory and descriptive research.

SOME ALTERNATIVES TO NATURALISTIC METHODOLOGY

Not every problematic behavior, nor every phase of any problematic behavior, lends itself to experimental investigation. Some behaviors are problematic not because they are exceptions to existing knowledge but, rather, because so little relevant knowledge exists. There is no substitution here for direct observation of the problematic behaviors. In the absence of explicit theoretical guidelines and substantive knowledge, an investigator may wish to explore, observe and describe some theretofore poorly understood behaviors (cf. Mead, 1936:283-5). Blumer must be commended for tenaciously reminding us there is no substitution for direct observation of behavior. But this may be accomplished in a manner which avoids many of the problems we have noted with naturalistic methodology. Mead's theoretical and methodological perspective suggests we abandon any concern with discovering the true nature or imminent meaning of any behavior; that we restrict the scope of behavior we attempt to observe and describe; and, that we establish some control over our own observing and recording behavior. We discuss each of these points and Melbin's (1972) exploratory-descriptive study of interpersonal behavior as a limited example.

Domains of Meaning

If the meanings of any object, event or activity are the responses made to it, no form of inquiry can fathom the "natural"

²² Important experiments which remain to be conducted include those which check for the extent of correspondence of other's response with the individual's reflexive response, which investigate the necessity and implication of such correspondence in a sequence of alternating and simultaneous coordinated actions, and, which examine the platform which "taking the attitude of the other" provides for imitation behaviors (cf. Lewis, 1979).

²³ We do not suggest that Mead's ideas are restricted to examination by psychophysiological experiments. We do suggest those ideas are complemented and extended by recent advances in neuro- and psychophysiological research on subvocal speech (Locke, 1970), on problem solving

(McGuigan, 1978; McGuigan and Schoonover, 1973), and on consciousness (John, 1976). Those theoretical and empirical advances may require radical alterations in the models of individual behavior which sociologists previously have assumed in their examination of interpersonal, group and social system phenomena. For one such alternative model which is generally consistent with Mead's approach, see Powers, 1973a; 1973b; 1978.

meaning, understanding or lawfulness of a phenomenon. Convergent responses may establish shared meaning, common understanding, and socially constructed lawfulness of any phenomenon. The observer and observed are likely to make similar responses to the latter's behavior to the extent they are operating with the same language and/or similar instructions for response. When they are not, the observer's responses to the behavior, and the explicit or implicit theoretical instructions occasioning the responses, constitute one domain of meaning for the behavior. The responses of the observed, and the occasioning instructions, constitute another domain of meaning. The investigating observer may wish to ascertain observed persons' responses to their own behavior, and the occasioning instructions, and may even wish to compare this domain of meaning with the observer's own responses. But neither domain is any more natural or less artificial than the other. One or the other, or both, may be more useful depending on the purposes at hand.

Scope and Control

The basic differences between experimental or systematic observation and exploratory-descriptive studies are not those of natural vs. artificial sites, phenomena or procedures. The differences turn on the scope of behavior one attempts to observe, the control one has over the behavior to be observed, and, the control one has over the observation of the behavior.

The experimenter has identified some specific behavior for observation, can locate or construct a situation in which the behavior can be produced or manipulated in accordance with the experimenter's theoretical directions, and, can control the observation and recording of his or her own behavior in relation to the behavior under investigation.

The alleged scope of naturalistic inquiry has always been very wide. But everything cannot be questioned at once (cf. Mead [1917] 1964:200) without eliminating some stable vantage point from which to

pursue investigation of that which is questioned. And everything cannot be observed at once! The human observer is a very limited instrument (Miller, 1956). The more persons to be observed, the greater the number of behaviors in which they engage and the greater the rate at which those behaviors occur, the less reliable the observer's record. If the investigator cannot control the behavior under observation, there must be a reduction in the scope of behaviors and actors to be observed.

The investigator's control over his or her own behaviors involves, at minimum, recording what she or he has done—where, when and how—to make and record the exploratory observations. "How did you know the behavior when you saw it?" This provides a basis for standardizing what the investigator does on successive occasions of observation or, equally important, knowing the baseline from which necessary changes or adjustments of criteria and procedure may be made. These same criteria and procedures constitute the directions by which others may do what the original investigator reports, may repeat those observations, and may confirm, revise or deny the original report. Melbin's (1972) research illustrates some of the advantages of a restricted scope of inquiry, and, of maintaining control over the investigator's responses to the behavior(s) of interest throughout the exploration, description and analysis of interpersonal behavior.

Melbin (1972:9) adopted a Meadian behaviorist stance by rejecting any concern with behavioral arousal, by assuming that living persons are always behaving, and by attempting to observe and describe their behavior and how it is directed in some ways rather than others. He began with the assumption that interpersonal acts commence with the behavior of one or more persons in a situation of sensory access to one or more other persons, and that acts continue or are completed with a variety of alternative reactions by one or more of those other persons. He therefore sought to describe systematically the situations established by the behaviors of one category of persons (psychiatric patients) and the probable alternative reactions of a

second category of persons (psychiatric aides).

Melbin conceded the absence of explicit a priori criteria for identifying beginnings, middles and endings of interpersonal acts. He could not identify the population and take a sample of such acts. Instead, he identified the population of sites of contact opportunities between patients and aides common to one state (3,000 bed) and one private (200 bed) hospital. He divided the waking hours of 7 A.M. to 11 P.M. throughout the week into two-hour periods. From this time-site matrix Melbin drew a sample of 54 observation periods (108 hours), yielding at least two periods per site per hospital. The sampled time-sites were visited and observations were recorded across a two-year span.

Four observers, including Melbin, were trained in criteria and procedures (1972:100-4) for recording surroundings, circumstances, participants' sex and approximate age, physical objects employed, and what was said and done. They attempted to "make exhaustive records in everyday English" whenever a patient's behavior, presence, or circumstance was followed by an aide's reaction. Observers were instructed (1972:103) to finish recording any sequence they had begun before turning to observe and record other developing episodes which might be more dramatic, and, to err on the side of "fuller pictures rather than sketchy" ones. Such observation and recording is demanding and exhausting, even with the restricted focus Melbin prescribed.²⁴ He concedes (1972:104) "it was a practical impossibility for an observer to note and enumerate all . . . the myriad aspects . . . [of all] . . . contacts between aides and patients." Nonetheless, this is one of the most systematic exploratory-descriptive field studies reported in the literature. With few exceptions, Melbin's criteria and procedures are exemplary and, with a sample of his findings, merit brief comment.

Six hundred seventy-eight sequences

were recorded in the two hospitals. These observations were weighted to adjust the actual hours of observation to the aides' 40-hour work week, for the relative number of aides present during an observation period, and, for the time of observation during the work shift of the day. Melbin estimates the weighted total number of act sequences to be 537 (private = 257; state = 280) for the two samples.

Melbin did not perform interobserver reliability checks during the field observations nor intercoder reliability checks during the classification of the observation data.²⁵ He does report the guidelines in terms of which observers were trained and observations were made. He also provides detailed criteria and procedures (1972:105-39) for classifying those observation reports into 26 categories of situations and 24 categories of simple reactions (1972:105-39).

Melbin's classification scheme orders 98% of his 537 observation records of patient-aide interaction. He reports the frequency [(S)] and probability [p(S)] of each of the 26 situations; the frequency [(R)] and conditional probability [p (R)] of simple and compound reactions to each of the situations; and the conditional probability of all pairs of situations and reactions [p (S) p (R)]. For example, the most frequently occurring situation (S) in the private hospital was a patient requesting

²⁴ Observers were trained to record only the behavior of aides in the presence of patients, and what the patients were doing at the time (Melbin, 1972:102). In the absence of aides, patient behavior was not recorded at all (Melbin, 1972:100).

²⁵ Given the random assignment of single observers to the different time-site locations, the former omission is less disturbing than the latter. It is not clear, however, why Melbin performed no check on the intercoder reliability of his classification system on at least a sample of the data. He did perform an interesting comparison of subjects' responses to his classification of observers' records of situations. Representative incidents of 25 of the categories of patient situations were typed on cards and presented to a sample of aides from the two hospitals. If they had seen such a situation they were asked to describe what the aide had done the last time the situation occurred. If, and only if, the reaction reported by the aide also had been reported by an observer, Melbin compared the two reports and used the language of the aide to mark the end-boundary of aide reactions to patient situations. Eighty-two percent of the reaction categories were established by such observer-aide correspondence. And, these categories subsumed 85% of the reactions recorded by the observers. Melbin offers this as evidence of the reliability of the estimated frequency of aide reactions in the population.

an item, service or information. The probability of this situation occurring was $p(S) = .118$.²⁶ The most frequent aide reaction (R) to this situation was fulfilling the request. The conditional probability of this reaction occurring to this situation was $p(R) = .810$.²⁷ The probability of this particular situation-reaction occurring among all pairs of situations-reactions was $p(S)p(R) = .096$.²⁸ Similar behavior descriptions are provided for simple and compounded aide reactions to the 26 categories of patient situations in the two hospitals. Melbin's (1972:154-86) rich data tables nicely illustrate some of the advantages of systematically observing, describing and becoming familiar with the phenomena we claim to study before proceeding to explain or predict those phenomena, or to produce them in conditions under our control.²⁹

Melbin sought to explore, observe and describe a poorly understood phenomenon: interpersonal behavior. He assumes the Meadian theoretical stance that the meaning of behavior is the response made to it (1972:68-85; 189-211), and he restricted the scope of inquiry to the description of aides' responses to patients' behaviors (1972:100, 102). Melbin emphasized controlled perception by instructing observers where (1972:94-6), when (1972:96-8), who (1972:99) and what (1972:103) to observe, and how (1972:103) to record those observations. He exercised further control by providing a detailed record (1972:105-39) of the devel-

opment and use of coding criteria for classifying the observation records into the categories used in his imaginative statistical analysis. He fails to provide interobserver and intercoder corroborative evidence, but he documents the steps by which observation and coding were accomplished, and by which, in principle, corroboration could be undertaken. Melbin's study is therefore an important advance in the development of rigorous exploratory-descriptive research, and a promising alternative to naturalistic methodology.

SUMMARY

We have challenged the long-standing assumption that Blumer's symbolic interactionist methodology is an extension and explication of "the Meadian tradition." Mead's characterization and analysis of scientific inquiry are strikingly different from Blumer's naturalistic methodology. We have attributed these epistemological differences to their diverse ontological assumptions. We have argued that Blumer's ontological assumptions contradict a basic premise of his symbolic interactionist theory. His naturalistic inquiry neither compliments nor extends Mead's methodological perspective.

We have challenged the related assumption that Mead's theoretical ideas are not amenable to systematic empirical examination. This assumption has arisen from a confusion of Blumer's symbolic interactionism with Mead's social behaviorism. Blumer's methodology does not lend itself to the investigation of Mead's ideas but those ideas have been investigated in a manner consistent with Mead's own methodological perspective. We have summarized several experimental investigations of Mead's notion "taking the attitude of other," one of them conducted by Mead's former student, Leonard S. Cottrell.

Finally, we have discussed several implications of Mead's methodological perspective for redressing some of the problems of naturalistic inquiry and have offered illustrations from Melbin's exploratory-descriptive study of interpersonal behavior. This research, like the ex-

²⁶ $p(S) = .118 = [(n = 30.15) \div (N = 256.57)]$; or, the number of times this situation occurred divided by the total N of situations which occurred in the hospital.

²⁷ $p(R) = .810 = [(f = 24.42) \div (n = 30.15)]$; or, the frequency of this specific reaction in this situation divided by the number of times this situation occurred in the hospital. Other reactions to this situation, and their probabilities, were: *refuses*, $p(R) = .136$; *teaches or corrects and then fulfills*, $p(R) = .017$; *teaches or corrects and then refuses*, $p(R) = .020$; and, *banters*, $p(R) = .017$.

²⁸ $p(S)p(R) = .096 = \{[p(S) = .118] \{p(R) = .810\}\}$; or, the product of the probability of this specific situation times the probability of this specific reaction in this specific situation.

²⁹ Such data also make possible Melbin's (1969) analysis demonstrating temporal and structural variations across the two hospitals in patients' unusual and routine disturbed behaviors.

perimental studies of "taking the attitude of other," has given attention to the behavior of the subjects and to the behavior of the investigator as well. Both foci are central to an understanding and investigation of Mead's theoretical and methodological perspective.

INCOME INEQUALITY IN THE FEDERAL CIVILIAN GOVERNMENT*

PATRICIA A. TAYLOR

Sweet Briar College; University of Virginia

American Sociological Review 1979, Vol. 44 (June):468-479

An analysis of income inequality by race and sex within the federal civil service yields three findings of importance for income attainment and human capital research. First, large differences in salary between minority/sex groups remain after occupational stream and a number of employment-related variables are controlled. Second, institutionalized discrimination explains only one-half of these salary differences. Finally, within the federal civil service, the pay structures of minority and nonminority women are more similar to each other than are the pay structures of any other two groups of employees.

The federal civil service, this nation's largest employer, has maintained by law a merit system of employment since the passage of the Civil Service Act in 1883. The initial impact of this legislation was to remove 10% of government jobs from political patronage and to establish a civil service in which employees were to be hired and promoted on the basis of job-related qualifications and merit. As of 1977, approximately 93% of all federal civilian employees were subject to merit regulations. A large body of executive orders and public laws now require that personnel actions in the federal civil service be free from discrimination on the basis of race, religion, national origin (Executive Order 8587, 1940; Executive Order 11478, 1969; and Public Law 92-261, 1972), sex (Executive Order 11478, 1969; and Public Law 92-261, 1972), and age (Public Law 93-259, 1974).

Given this long history of regulations

prohibiting employment discrimination, as well as the role of the federal government as a model employer (Mosher, 1965: 170-1), we would expect that the federal civil service would show less income inequality between minority/sex groups than the private sector, and some limited research tends to support this expectation (Smith, 1976). Moreover, as the federal bureaucracy is the instrumental organ for the implementation of federal laws and regulations, it is more sensitive to both congressional scrutiny and public criticism than the private sector, and thus more likely to enforce nondiscrimination laws. Finally, a number of federal services such as the biennial census, income tax collection, interstate commerce regulation, etc., are provided by no other organizations. Therefore, agencies of the federal government cannot argue that discriminatory clientele would go elsewhere if the agencies should hire and advance minorities and women. Thus, equal employment opportunity should be implemented in the federal civil service, if anywhere.

This paper examines data on the federal civil service to address three questions of major importance in studies of income inequality: (1) within one employment context, how much income inequality by race and sex exists; (2) what amount of income inequality might be attributed to employer discrimination; and (3) how much income inequality by race and sex remains after placement into job streams is controlled?

The author wishes to acknowledge the helpful criticisms of two anonymous reviewers at the *ASR*; the comments of Nathan Kantrowitz, Murray Milner, Robert Stump, and Paul Wilken; the programming assistance of Dale Child and Paul Twohig; and the preparation of the manuscript by Gail Wooten Votaw. Part of this research was conducted under NIE-G-78-0005, a research grant from the Department of Health, Education, and Welfare. The findings and opinions expressed are those of the author and should not be construed as representing the opinions or policies of any reviewer, or any agency of the federal government.

Income Inequality in Employment

Numerous studies in human capital analysis and in the status attainment literature have pointed to the importance of education, years of work experience, and other labor market variables as determinants of income attainment (Becker, 1957; Becker and Chiswick, 1966; Duncan, 1969; Mincer, 1970; Kluegel, 1978; Oaxaca, 1973; and Smith, 1976). Generally, three underlying themes have emerged from studies of income inequality.

First, there is an assumption that different rewards given to different race, sex, or ethnic groups for equal amounts of education, experience, etc., may be *prima facie* evidence of the failure to apply the principle of achievement in a universal manner. Adherence to the principle of achievement rather than ascription requires that workers be evaluated on the basis of their productivity rather than on the basis of race, sex, or other ascribed characteristics. Hence, human capital analysis as formulated by Schultz (1961) and Becker (1964) has received widespread attention not only because of its theoretical and methodological parallel to analyses of physical capital, but also because of its intuitive appeal to an egalitarian argument in studies of income inequality. A growing body of research in this area has found, for example, that blacks receive a lower return to education than do whites (Becker, 1966; Weiss, 1970; Harrison, 1972; Jencks, 1972; Welch, 1973; and Kluegel, 1978); that women receive a lower return to education than do men (Malkiel and Malkiel, 1973; Oaxaca, 1973); that, net of education and other job-related variables women and blacks receive lower salaries than do men and whites (Suter and Miller, 1973; Smith, 1976); and that the quality of schooling may not account for much of the difference in returns to education (Weiss, 1970).

The issue of achievement versus ascription has undergone increasing scrutiny by a number of researchers (cf. Butler, 1976), especially when the concept of structural and/or institutional discrimination is invoked to explain income inequality. Explanations of inequalities among groups

often make use of the concept of institutional discrimination, as distinct from individual racism, sexism, or the like (see Benokraitis and Feagin, 1974; Yetman and Steele, 1971, for reviews). A common feature of such explanations is the argument that inequality is, to a considerable extent, a result of the equal application of universalistic criteria to groups that meet these criteria unequally (Jones, 1972; Yetman and Steele, 1971; 363-7). Black students denied admission to college because of low scores on standardized tests, women earning lower salaries than men because they have less on-the-job experience, and Hispanics who are passed over for employment or promotion because they lack the educational requirements of the position—all these might be viewed as instances of institutional discrimination through the use of merit standards universally applied.

Recently, Butler (1976) has criticized this view of inequality, while suggesting that the universalistic criteria of educational level and aptitude test score do not account for the observed differences in promotion time between black and white enlisted men in the U.S. Army. He concludes that "the black enlisted man is subject to inequality which is not the result of failure to meet universalistic criteria, i.e., indirect impersonal institutions, but rather a result of the direct racist actions of real life people" (Butler, 1976:817). The continuing discussion of black-white and male-female differences in the socioeconomic achievement literature attests to the importance of such an issue (cf. Hauser, 1978; Butler, 1978).

These studies have relevance for merit employment in a civil service system. For example, if education is used to assign level of work which in turn determines salary, then equal levels of education should produce equal salaries for each minority/sex group, *ceteris paribus*. In short, the economic returns to education, work experience, and other employment-related variables for various minority/sex groups may be compared to determine the extent to which a merit employer adheres to stated principles of equality of opportunity.

A second emergent theme of studies of income inequality is that the structure of labor markets may influence the avenues of mobility, monetary returns to education, and so forth (Bowles and Gintis, 1976; Kaysen, 1973; Kluegel, 1978). Therefore, assessment of discrimination is difficult since differences between employers may mask important effects. For example, work experience within one firm may not be fully credited toward salary in another firm; years of schooling may be more important to one employer than another; and positions of authority may vary in the exercise of control. Unless specific attention is given to these differences, studies across various employers may be misleading.

Doeringer and Piore's (1971) concept of the internal labor market directs attention to just such issues (see also Caplow, 1954, on the bureaucratic labor market). In an internal labor market, employees and the employer are to some extent shielded from direct economic influences of the external labor market (whether national, regional, or local) by the stability of established personnel practices and worker/management relations. The internal labor market has clearly defined ports of entry, specifiable career ladders for advancement, and regulations governing entry and progression. In short, the ideal-type internal labor market is a rationalized economy in which personnel regulations are made explicit and are applied in a universal manner.

To the extent that an internal labor market can be identified, a number of confounding effects in studies of discrimination can be eliminated.

A third, but no less important theme of income inequality studies, is that job placement may be of critical importance in discerning possible discriminatory patterns. For example, the concentration of employees by race (or sex) into trade occupations which have especially protective unions may affect studies of income inequality (cf. Ashenfelter, 1972; Snyder and Hudis, 1976). Race differences in the general allocation of occupations may alter the relationship of salary, education, and occupational placement (Duncan, 1969). To the extent that career lines exist

within occupations or groups of occupations which have different earnings, an employee's salary is limited in no small measure by occupational placement (cf. Spilerman, 1977).

The mechanism by which minorities and women become concentrated in particular occupations is not well understood (Snyder and Hudis, 1976). However, within one internal labor market we would reason that the employer has considerable control over the placement of individuals into particular job streams. That is, the employer allocates applications for employment to specific hiring pools, such as job registers categorized by type of work and level of expertise. Once hired into a particular job stream, internal staffing regulations may "track" employees for the duration of their career with the employer. Such tracking may operate to segregate women into low-paid clerical occupations, for example, or minorities into technical occupations. Should such occupational placement occur, then some of the salary differences between minority/sex groups may be attributed to employer discrimination rather than institutional discrimination.

However, the separation of institutionalized discrimination (i.e., employee characteristics) from employer discrimination (i.e., job placement, supervising positions, etc.) is rarely made. Employment data within one internal labor market would provide the basis for such an analysis. Recent data on federal civilian employees made available by the U.S. Civil Service Commission allow for a study of possible minority/sex differences in salary within one labor market.

Data and Method of Analysis

A one-in-one hundred sample of the full-time white-collar federal civilian work force was drawn from the U.S. Civil Service Commission's automated data files. The salaries of active white-collar employees as of June 1977, were analyzed by regression analysis.

Approximately 70% of the 2.5 million federal civilian employees are included in the white-collar work force, the remaining

employees are in the wage grade. The personnel policies which affect these employees derive from a long history of congressional legislation, Executive Orders, and Civil Service Commission regulations which require: (a) equal pay for substantially equal work (Classification Act, 1949); (b) personnel actions free from discrimination; and (c) federal pay systems commensurate with private pay systems (Pay Comparability Act, 1970). These laws along with regulations issued by the Civil Service Commission through the *Federal Personnel Manual* generate in effect a single (albeit large and heterogeneous) internal labor market (cf. Doeringer and Piore, 1971). Although there may be different job streams and career lines, the standards for job classification by type of work, difficulty of work, etc., are set by law and Civil Service Commission policy, so that across occupations or career lines, jobs of equal levels of difficulty, responsibility and so forth should receive equal remuneration. Therefore, analysis of the white-collar workers in the civil service holds constant various influences which might otherwise confound a study of employment discrimination.

Salary in dollars is the dependent variable for this analysis. Additional variables which may affect the salary of an employee and/or the operations of the internal labor market are given below.

Education is measured by the number of years of schooling completed and varies from 4 years of schooling to 22 years for postdoctoral work. *Supervisory status* is used here as a dummy variable, with the value of 0 for a nonsupervisory position, and 1 for a supervisory position. *Age* is determined by year of birth and varies from 18 to 70. *Years of federal service* varies from 0 to 50 years of experience in the federal government. This variable also includes years of military service, and as such, would tend to bias upwardly the years of work experience for men as opposed to women, since men are far more likely to have spent time in the military. As both age and years of work experience are known to have a nonlinear relationship with earnings (Becker, 1964:7-8; Mincer, 1974), squared terms for both age and

years were used in this analysis as additional controls.

Three additional variables are of particular importance to the federal labor market. First, *Position* occupied is entered as a dummy variable and indicates whether the position currently held by an employee is in the competitive (1) or excepted (0) service. Excepted service positions are specified by laws and regulations, and although most excepted positions fall under some merit system, these regulations differ somewhat from those covering the Civil Service Commission's competitive service. Excepted service employment is noteworthy in that an incumbent earns no reinstatement eligibility and both appointment to and removal from office are easier in the excepted than in the competitive service. Veteran status is also included by the use of two dummy variables. *Disabled veterans* are those persons who have a compensable or service-related disability. *Other veterans* are those persons who served in the armed forces; who are the spouse or mother of a veteran with a service-connected disability; or who are the widow, widower, or mother of a deceased wartime veteran. Veteran status is important in the federal civilian service as those who qualify for a veterans' preference receive preferential consideration in hiring when competing from a civil service register and at times during reduction-in-force. To control for region, a dummy variable for location of employment (D.C.) is used to identify those who are employed in the District of Columbia and its surrounding area, or in the field. As the heads of federal agencies are located in D.C., as well as other highly graded staff positions, location in D.C. may be related to higher salaries.

Finally, four minority/sex groups have been identified by crossing sex with minority status. Those persons who are identified as Negro, Spanish-surnamed, Oriental, American Indian, Aleut, or Eskimo are classified as minority employees; any other employee is classified as non-minority.

There are four steps in this analysis. First, in order to assess the additive relationship of minority/sex groups to salary with job stream controlled, a regression

analysis is performed within five occupational groups of the white-collar work force—professional, administrative, technical, clerical, and other. Second, differences in pay structure across minority/sex groups are examined through regressions performed within minority/sex categories. Next, differences in predicted salary for the four minority/sex groups are obtained from the latter regression analyses by systematically varying the assumptions that might plausibly be made about pay structures and mean values. Finally, the decomposition of differences in salary due to different group characteristics and different pay structures is presented.

Results

The results of the first data analyses are presented in Table 1. For each occupational group, a regression analysis was performed using salary as the dependent variable. Ten independent variables were introduced to control for factors which might affect the relationship of minority/sex status and salary. After the independent variables were entered, dummy variables for nonminority females, minority males, and minority females were entered into the analysis. As nonminority male is the deleted category among the minority/sex groups, the unstandardized regression coefficient for each of the other minority/sex groups represents the salary differences between nonminority males and a specific minority/sex group.

As shown in Table 1, the explained

variance for the regression analyses ranges from $R^2 = .456$ for administrative to $R^2 = .793$ for clerical workers, for federal employees as of June 1977. These relatively large R^2 's suggest that most of the variation in salary has been statistically explained by the variables used here.

The total regression analysis includes all white-collar employees as specified earlier. With variables such as age, years of federal service, and education controlled (as well as a number of other employment-related variables), there exist considerable salary differences between nonminority males and other minority/sex groups. On the average, minority males earn \$1,994 less than nonminority males; nonminority females earn \$3,476 less; and minority females, \$3,970 less. When occupational groups are analysed, separately there are still notable differences as between minority females and nonminority males in the professional category where minority females earn \$5,172 less than nonminority males. Even though differences between the four groups diminish in the case of some occupational groups (as, for example, among clericals), no minority/sex group surpasses nonminority males in average salary.¹

¹ A significant obstacle to an analysis of inequality within one segment of a labor force is that (to paraphrase Hauser, 1978) there is no closure in the civil service population with respect to movement out of the Civil Service. That is, if termination of federal employment varies by minority/sex groups, especially if this outflow also varies by qualifications and/or ability, then estimates of inequality will be misstated.

Table 1. Cost of Discrimination among Federal Civil Servants, for Active Employees, 1977

Occupational Group for Active employees, 1977	N	R^2	Net Economic Detriment in Dollars ^a		
			Nonminority Females	Minority Males	Minority Females
Professional ^b	2,690	.557	-5,156	-831	-5,172
Administrative ^c	3,321	.456	-3,909	-1,519	-4,862
Technical ^c	2,924	.542	-1,587	-1,673	-2,320
Clerical ^c	6,705	.793	-396	-623	-695
Other ^d	272	.540	-480	-524	-1,107
Total ^c	15,912	.603	-3,476	-1,994	-3,970

^a Regression b's for each minority/sex group are net of age, square of age, position occupied, D.C. or field, supervisory status, disabled veteran, other veteran, years of federal service, square of years of federal service, and educational attainment.

^b All coefficients and the model are significant at the $p \leq .001$ level, except for minority males, $p \leq .112$.

^c All coefficients and the model are significant at the $p \leq .001$ level.

^d None of the minority/sex coefficients obtained statistical significance, although the model itself was significant at the $p \leq .001$ level.

Actually, the salary differences between nonminority males and other groups are likely to be larger than those presented in Table 1, since the different groups may have not only different mean values of education, work experience, and so forth, but also different pay structures, or rates of return. The regression equations in Table 1 represent the best-fitting *joint* pay structure, with only the additive effects of minority/sex group considered. In order to assess the pay structure of each minority/sex group separately, economic inequality will be analyzed using a method of indirect standardization discussed by Althausen and Wigler (1972), and variously employed by Duncan (1969), Smith (1976), and Kluegel (1978), among others. Basically, we are asking the following question: What part of the salary differences for active employees between nonminority males and other groups is due to the fact that each group has different levels of education, etc., and what part may be due to different pay structures? For example, the human capital model of returns to schooling would suggest that if nonminority males had higher levels of education, they would be more productive workers, and therefore, would receive a higher salary (Welch, 1973). To the extent that the various minority/sex groups have similar levels of education (as well as other characteristics) but receive different salaries, then the groups must have different pay structures. The existence of different pay structures which are determined by the employer may be evidence of the failure to

apply standards of merit in a universal manner.

Two regression models predicting salary are presented in Table 2. The first model contains variables common in human capital analyses; age, square of age, years of federal service, square of years, veterans' preference, location in D.C., and level of education. Model II includes the above variables and adds those employment attributes over which the employer exercises considerable control: supervisory status, position occupied (competitive or excepted), and occupational group (entered as a set of dummy variables for administrative, technical, clerical, and other groups with the professional as the omitted category). These last three variables are of special interest, for by controlling these three factors, we are assuming that placement into job streams has been made without regard to minority group or sex.

While the analysis presented here is not directed toward assessing the returns to particular employment characteristics, some brief comment on the results presented in Table 2 is in order before proceeding to the decomposition of salary differences into institutional and employer discrimination.

First, consistent with the findings of studies cited earlier, the monetary returns to age, education, years of federal service, and employment in the D.C. area are all higher for nonminority males than for any other group in both Model I and Model II. The more negative coefficient for nonminority males on the disabled veterans variable compared to the coefficients for the other groups may indicate that the "handicaps" of race, sex, and physical disability are not strictly cumulative in their effect on salary. The other veterans dummy variable also has a negative impact on salary. This result may suggest that the veterans' preference, applied at entry to the federal service, places individuals of lower ability into jobs for which they would otherwise not qualify, while subsequent promotions are affected more by ability than by the veterans' preference. If so, then the larger absolute value of the coefficient for nonminority males may mean that the salary return to a given

To assess the possible differences between the active population and the terminating population, a regression analysis of the outflow population from June, 1975, to June, 1977, was undertaken. The amount of salary disparity between nonminority males and the three minority/sex groups is substantial for the total sample of terminators, although the differences between minority/sex groups are not quite as large as in the active population. Among terminators, minority females earn approximately \$2,658 less than nonminority males; minority males earn \$1,762 less; and nonminority females, \$2,750 less. Similar results are also obtained when terminating employees are analyzed separately by occupational group. Therefore, the impact of differential rates of termination by ability and minority/sex group should have little impact on further analyses of salary differences.

^e All variables except disabled vet, square of age, and administrative significant at $p \leq .001$; square of age significant at $p \leq .01$.

level of ability is larger for that group than for the other three groups. The remaining results from Model II indicate that differences in the returns to supervisory status and occupational stream are generally greater between males and females than between the two ethnic groups within either sex. Finally, the salary advantage of employment in the excepted service is greater for minorities and women than for nonminority males. It should be reiterated, however, that excepted positions, while carrying a net salary advantage according to these findings, are also subject to fewer employment safeguards. The resultant job insecurity may or may not fall equally on members of different minority/sex groups.

In summary, then, the results of the separate regression analyses in Table 2 suggest that each minority/sex group has a substantially distinct pay structure which, in part, contributes to different average salaries for the four groups.

The separate regression analyses just

discussed permit the decomposition of salary differences by minority/sex group into institutional and employer components. The method to be used involves predicting salary for each of the minority/sex groups while systematically varying the mean values and pay structures as in Table 3 (cf. Malkiel and Malkiel, 1973; Kluegel, 1978). When salary is predicted for each group using its own pay structure and own mean values for the independent variables, considerable differences are apparent. Nonminority females earn only 62.6% of the salary of nonminority males; minority males earn 80.6%; and minority females earn 62.3%. Even when occupational group is controlled as in Model II, there remain substantial salary differences between nonminority males and the other groups.

Part of these salary differences are due to the fact that each group has different levels of educational attainment, supervisory status, age, and so forth. In fact, if all groups had the same mean values as

INCOME INEQUALITY IN THE FEDERAL CIVILIAN GOVERNMENT 475

Table 3. Predicted Salary (in Dollars) for Four Minority/Sex Groups in Two Models (Varying Pay Structure and Mean Values)

Model	Minority/Sex Group						
	Nonminority Males	Nonminority Females		Minority Males		Minority Females	
Model I for Salary Predicted From:	A	B	B/A in %	C	C/A in %	D	D/A in %
(1) Own Pay Structure and Own Mean Values	18,508	11,593	62.6	14,917	80.6	11,539	62.3
(2) Own Pay Structure and Non- minority Male Mean Values	18,508	14,083	76.1	16,139	87.2	13,397	72.4
(3) Nonminority Male Pay Struc- ture and Own Mean Values	18,508	15,242	82.4	17,233	93.1	15,363	83.0
Model II for Salary Predicted From:							
(1) Own Pay Structure and Own Mean Values	18,411	11,718	63.6	15,642	85.0	10,908	59.2
(2) Own Pay Structure and Non- minority Male Mean Values	18,411	14,896	80.9	17,872	97.1	13,731	74.6
(3) Nonminority Male Pay Struc- ture and Own Mean Values	18,411	13,884	75.4	16,162	87.2	13,681	74.3

nonminority males, the salary differences would be substantially reduced as the data on line (2) suggest. From the substitution of nonminority male mean values into the regression equations for each of the minority/sex groups, we can obtain an estimate of what each group would receive in salary if all groups had levels of educational attainment, years of federal service, etc., equal to nonminority males. The estimates in Table 3 show that minority women would earn less than three-fourths of the salary of nonminority males, while minority males would earn 87.2% of the average nonminority male salary. However, if all groups were compensated at the same rate as nonminority males (i.e., all groups had that pay structure), the salary differences between nonminority males and the other groups also would be reduced considerably as indicated in line (3). The computations in line (3) compared with those of line (2) suggest that pay structure has a substantial impact on the salary differences between minority/sex groups. If all minority/sex groups had the identical pay structure as nonminority males, the salaries would more nearly approximate nonminority males than if their mean values were equal to nonminority males but their own pay structure was intact.

The data presented for Model II are of note in that, first, minority males come

very close to parity with the salary of nonminority males when placement variables have been controlled. However, both groups of women appear to fare even worse under the assumption of equality of job placement, although this pattern is not completely consistent.

In important respects, differences due to employee's mean values may be taken as analogous to the concept of institutionalized discrimination whereas differences due to pay structure may correspond to employer discrimination. Table 4 compares the percentage of the salary differences due to different characteristics with the percentage due to different pay structures, using the method of indirect standardization employed by Malkiel and Malkiel (1973) and Smith (1976). To obtain the entries in Table 4, we performed the following computations on the data presented in Table 3:

$$\begin{aligned}
 &\text{Gross difference in mean salary} \\
 &(\text{nonminority females}) = (1)A - (1)B; \\
 &\text{Difference due to different mean values} \\
 &(\text{nonminority females}) = (3)A - (3)B; \\
 &\text{Difference due to different pay structures} \\
 &(\text{nonminority females}) = (3)B - (1)B.^2
 \end{aligned}$$

² There is an index number problem presented in this method of analysis since there are two sets of regression equations and two sets of mean values by

Table 4. Analysis of Salary Differences between Nonminority Males and Other Minority/Sex Groups (Assuming Minimum Differences Due to Pay Structure)

Source of Salary Differences in:	Minority/Sex Group					
	Nonminority Females		Minority Males		Minority Females	
	Dollars	%	Dollars	%	Dollars	%
Model I						
Gross Difference in Mean Salary with Nonminority Males	6,915	100.0	3,591	100.0	6,969	100.0
Difference Due to Different Mean Values	3,266	47.2	1,275	35.5	3,145	45.1
Difference Due to Different Pay Structures	3,649	52.8	2,316	64.5	3,825	54.9
Model II						
Gross Difference in Mean Salary with Nonminority Males	6,693	100.0	2,769	100.0	7,503	100.0
Difference Due to Different Mean Values	4,527	67.6	2,249	81.2	4,730	63.0
Difference Due to Different Pay Structures	2,166	32.4	520	18.8	2,773	37.0

The findings reported in Table 4 make it clear that a considerable portion of the salary differences between nonminority males and other groups may be due to different pay structures. Looking only at

which to standardize. That is, we could perform the following computations and obtain decomposition estimates:

Difference due to mean values (nonminority females) = (2)B - (1)B;

Difference due to pay structure (nonminority females) = (2)A - (2)B.

These computations would yield smaller estimates of salary differences due to mean values and larger estimates due to differences in pay structure, especially for both groups of women. The percentage entries for Table 4 would be as follows:

	Non-minority Females	Minority Males	Minority Females
Model I			
Difference due to different means	36.0	34.0	26.7
Difference due to different pay structures	64.0	66.0	73.3
Model II			
Difference due to different means	47.5	80.5	37.6
Difference due to different pay structures	52.5	19.5	62.4

The actual amounts of salary disparity which are due to differences in mean values and pay structures fall somewhere between these figures and those presented in Table 4; the latter were selected for discussion in the text since they give the more conservative estimate of employer discrimination.

Model I we find that minority males, on the average, make \$1,275 less than non-minority males due to their different characteristics. However, another \$2,316 (or nearly two-thirds of the total salary difference) is due to different returns to their investments. For the two groups of women, we find that over half of their salary differences with nonminority males is due to different returns when level of investment has been held constant.

If we examine Model II, which controls for placement into job stream, salary differences due to different pay structures are lowered considerably. Nonetheless, differences in salary due to pay structures vary from 18.8% for minority males to 37.0% for minority females. This finding is partially consistent with Spilerman (1977), who argues that occupational placement is a key element in the determinants of earnings. That is, if placement into job streams is performed using only merit criteria universally applied, then income inequality should always be assessed "net of" job stream (assuming there should be different pay for different jobs). If, however, sex and/or race is used to determine job suitability, then job placement itself becomes a suspect personnel decision and contributor to income inequality.

Discussion

The findings presented in this paper make possible several observations on

race/sex income inequality. First, salary differences between minority/sex groups are considerable with a large number of employment-related variables controlled. Even when placement variables are controlled, these differences remain.

What can explain these salary differences? It may be too facile merely to argue that individual racism and sexism are the causes of all differences in the pay structures found here. There is, for example, no direct measure of ability used here. Furthermore, we have no estimate of work experience in the private sector. However, entry into the federal service is generally accomplished through a standardized test on which all persons must perform well before they can gain employment, and most of the effects of private experience should be captured in the controls for age and the square of age.

Moreover, the variables used to control for differences between the minority/sex groups are implicitly assumed to operate in a nondiscriminatory manner. Yet the very opposite may be true. For example, supervisory status has been shown to have an effect on salary and to vary by minority status (Kluegel, 1978). If supervisory positions are allocated in a discriminatory manner in the federal government, then by controlling its effect, we have eliminated one nonmerit source of income disparity due to pay structure. Similarly, differences in salary may occur through discriminatory placement into occupational streams as noted earlier. However, our purpose in this research was to make as strict an examination of salary differences as possible. In this manner, we can be relatively certain that we would not overstate the presence of employer contributions to salary disparities. That is, this method allows for the possibility of group preferences or dispositions toward particular work situations (i.e., it might be possible that women *prefer* clerical jobs to others; that minorities *prefer not* to be supervisors, etc.). It is more likely, of course, that placement into job stream is a function of both the employer's decision regarding an employee's ability, and a preference expressed by an employee. Therefore, the amount of pay disparity due to differences in pay structure prob-

ably falls somewhere between the estimates from Model I and Model II.

We have also seen that the standardized salary difference between nonminority and minority women is considerably smaller than the difference between any other two groups. That is, minority women resemble nonminority women more closely than minority women resemble minority men, although the pay structures of the two groups of women are less similar when job placement is controlled. Nonetheless, minority women receive lower returns to education as well as a lower percentage of the nonminority male salary than any other group. At a pragmatic level, these findings are of obvious importance to equal employment opportunity efforts, as well as being instructive with respect to the ascriptive nature of our society.

Third, these findings can be related to the private sector of the economy and the presence of possible minority/sex discrimination there. As noted earlier, some limited evidence (Smith, 1976) and considerable plausible conjecture would suggest that discrimination by race and sex in the private sector substantially exceeds that reported here for the federal service.

Finally, these data bring indirect evidence to the debate surrounding returns to education and quality of schooling. The results of studies of returns to education by minority groups show such large differences between blacks and whites that we might wonder whether black education should be discounted two to three years if it is of poorer quality than white education (see Stolzenberg, 1975). However, we know of no conventional wisdom that claims that the quality of minority male education is substantially higher than the quality of minority female education (and similarly for nonminority males and females). Yet the returns to schooling vary more by sex within one minority group than within either sex group. While this pattern may be affected by particular occupational placement, the fact that both groups of women have lower returns to education than do either group of men does itself raise questions regarding the quality of schooling argument.

Conclusions

In general, this research has confirmed the existence of minority/sex disparities within an employer which has a long history of attempts to manage its personnel system in a meritorious manner. Such salary disparities exist thirteen years after the passage of the 1964 Civil Rights Act, and eight years after Executive Order 11478. While employers are required to do little with regard to individual characteristics a worker brings into the labor market, the results in this study suggest that as much as one-half of the salary disparities between minority/sex groups could be eliminated in future cohorts of employees by changes in employer practices alone.

In particular, this study lends strong support to the contention that the concept of institutional discrimination should be carefully reexamined. To be sure, there are situations in which the concept is straightforward—as, for example, in the *proper* use of standardized aptitude tests for employment selection. However, when universalistic criteria must be applied according to the discretion of an individual decision maker, as is often the case in personnel actions, the evidence presented in this research suggests that what is called institutional discrimination may be an unexamined pretext for employer discrimination.

SUBURBAN CHANGE AND PERSISTENCE*

ANDREW COLLVER

State University of New York at Stony Brook

MOSHE SEMYONOV

University of Nebraska

American Sociological Review 1979, Vol. 44 (June):480-486

A method for the quantitative analysis of change is developed, and demonstrated by a study of changes in the socioeconomic status (SES) characteristics of 89 Long Island suburban communities 1960-1970. Three theoretical models in the literature on suburban change are shown to be related to statistical measures of change of the mean, change of dispersion and positional change. Because of failure to recognize that there are three mathematically independent dimensions of change, high correlations between measurements of a status characteristic at two points in time were formerly misinterpreted to mean a lack of change. Also, previous studies probably erred in generalizing from only one indicator of suburban SES, educational attainment. In this study, three SES variables, education, occupation and income, are shown to have different patterns of change on the three dimensions.

Change and persistence are complementary aspects of every active, open system of relationships. Whether a system is to be described as changing or stationary depends on the conceptual and time frames within which it is viewed and the sensitivity of the instruments for detection of change. Too often, different observers of the same phenomena will offer conflicting or contrasting interpretations of change because they begin from different theoretical positions or use different methods of measurement, or both. Our purpose here is to develop and demonstrate the use of a method for analysis of change that will resolve apparent disagreements between theories, help to clarify the relations between different theoretical perspectives and tighten the logical connections between theory and evidence.

The field selected for a demonstration of the method is the study of change of socioeconomic status (SES) characteristics of American suburbs. In the literature on this subject we find three dis-

tinct perceptions. Some investigators see trends of rising or falling average status of suburbs; others perceive a widening range of inequality between rich and poor suburbs; and still others are impressed by the tendency of suburbs to maintain their relative positions in terms of socioeconomic status. All three views are supported by empirical data and persuasive theoretical arguments, and yet they seem inconsistent with one another, if not contradictory.

Three Conceptual Approaches

In a paper entitled "Suburban Persistence," Farley (1964) found high correlations between suburbs' earlier and later educational characteristics. In this, his findings and discussion were consistent with those of B. Duncan (1964), and Taeuber and Taeuber (1965:174). Interpreting the high correlations as "persistence," Farley concluded that suburbs tend to retain their socioeconomic characteristics over long periods of time. In a large-scale replication of Farley's study, Guest (1978) again demonstrated persistence, but like Farley, had some difficulty interpreting the findings in relation to theories of urban ecology. Farley (1964:47) remarked that his findings were consistent with Burgess's (1925) concentric zone model, but then went on to say that "... once a suburb is established, the population that moves into that suburb tends to resemble the population already

* Direct all communications to: Andrew Collver; Department of Sociology; State University of New York at Stony Brook; Stony Brook, NY 11794.

This is a revised version of a paper presented at the annual meeting of the American Sociological Association, San Francisco, 1978.

Critical comments by R. W. Hodge, Andrea Tyree and John Logan are appreciatively acknowledged. Linda Sterns collaborated in collection and preparation of data.

living there." Guest found the latter conclusion in conflict with Burgess's notion that successive in-migrants tend not to be of the same status as the existing residents. As we shall show, however, the difficulty of reconciling the empirical findings with theory is easily avoided, for before-after correlations of status variables cannot be predicted from the Burgess model.

The concentric zone model (Burgess, 1925; Hawley, 1950; Hoover and Vernon, 1962; Schnore, 1972; Guest, 1974) describes the dynamics of a region continually in the process of change. According to this model, neighborhoods are likely to go through a life cycle in which the older and more centrally located neighborhoods experience a decline in their relative socioeconomic status, caused by invasion and succession by lower status groups as higher status residents move farther from the city center. The initial growth of the outer suburbs may produce a marked rise in status as compared with the older rural communities that they engulf. As will be shown, this model is not incompatible with the suburban persistence model, once both are correctly understood in mathematical terms. If the tendency of established suburbs is to decline gradually in SES as they age, the result to be expected is the subtraction of a constant from each suburb, affecting the mean but not the correlation coefficient, which is sensitive only to standardized deviations from the mean.

A newer model of suburban development, which we will call the "theory of consolidation advantages," leads to the expectation of a widening gap between rich and poor suburbs. In this model, as described by Logan (1976; 1978), communities seek to affect the growth process in order to maintain or create inequalities among localities to their own advantage. Places with early advantages, by making full political use of their resources, can reinforce and improve their relative positions within the system of places. At first this theory may appear to be inconsistent with the suburban persistence findings. On closer examination, however, we find that it assumes or requires a high degree of persistence in combination with increas-

ing dispersion.¹ It is a pattern of change that cannot be measured by the correlation coefficient alone.

Is the differentiation of suburbs by SES persistent, or is it changing? Neither theories nor research methods have offered clear answers to this question, largely because theories tend to focus on only one or another aspect of change and because the tools used for analysis of change have not been designed appropriately for the purpose. A conceptual model is needed that will deal with all dimensions of change, and the statistical tools employed should enable us to answer the following three questions: (1) Have the averages of SES characteristics of suburbs increased, decreased or stayed the same (Burgess model and other evolutionary theories)? (2) Have the differences between suburbs widened or narrowed (Logan's consolidated advantages model)? (3) To what degree have the individual suburbs maintained or changed their relative positions in the status hierarchy (Farley's suburban persistence model)?

By simultaneously examining all the dimensions of suburban differentiation, we should be able to formulate a more complete understanding than is provided by any one approach. In the following analysis we develop a method for measuring three components of change and demonstrate its use with data from one suburban region 1960-1970.

Descriptive Overview

The suburbs taken for this comparison are 89 communities of Nassau and Suffolk counties, Long Island, New York, in 1960 and 1970. The variables selected as descriptors of these communities are *education*, median years of school completed,

¹ In quantitative terms, if a linear model is assumed, the consolidated advantages hypothesis says that the unstandardized regression coefficient, b_{yx} , is greater than 1—that the value, Y , of a variable at t_2 is predicted by the regression line to be farther from the mean than its previous value, X , was at t_1 . Since $b_{yx} = r_{yx} s_y/s_x$, we can see that achievement of a slope greater than 1.0 requires high enough values of both r_{yx} and s_y/s_x to produce a product greater than 1.0. Assumption of a curvilinear relation between Y and X would require appropriate modifications of the preceding.

Table 1. Means and Standard Deviations (Unweighted) of SES Variables for 89 Long Island Communities, 1960 and 1970

	Median Years School	Pct. Upper White- Collar	Median Family Income
\bar{Y} 1970	12.61	39.54	\$12,192
\bar{X} 1960	11.95	36.89	8,683
s_y 1970	.90	14.84	4,732
s_x 1960	.98	14.72	2,121
\bar{Y}/\bar{X}	1.05	1.07	1.404
s_y/s_x	.92	1.01	2.231

for the population aged 25 and over; *occupation*, percentage of the male civilian employed labor force in the upper status, white-collar occupations of professional, technical and kindred workers and managers, proprietors and officials, excluding farm; and *income*, median family income in 1959 and 1969, corrected for inflation in 1969.²

Data were obtained from publications of the U.S. Census of Population and Housing. Of the 144 places in the two-county region with over 2,500 population in 1970, 89 had comparable data for the two census dates. All 89 had over 2,500 inhabitants in 1960. Data for the analysis were taken directly from the census or computed from census tabulations, except that median family incomes in 1960 had to be estimated for 12 high income communities of less than 10,000 population.³ Unweighted means and standard deviations of the three SES variables are shown in Table 1.

Means of all three variables increased during the decade, slightly in the case of education and occupation, and very substantially in the case of income (corrected for inflation). The standard deviation of education decreased slightly, that for occupational status remained virtually unchanged and the standard deviation of median family income, in 1959 dollars, more than doubled. The increase in dis-

Table 2. Correlation Matrix of 1960 and 1970 Values of SES Characteristics, for 89 Long Island Communities

	X1 Educa- tion 1960	X2 Occu- pation 1960	X3 Income 1960	Y1 Educa- tion 1970	Y2 Occu- pation 1970	Y3 Income 1970
X1		.839	.777	.783	.754	.663
X2			.929	.839	.910	.857
X3				.820	.867	.898
Y1					.819	.867
Y2						.869

person was greater than the increase in the mean of family income so that the standard deviation increased not only in absolute terms but increased relative to the mean.

Correlations between the 1960 and 1970 values of SES variables are given in Table 2. At the zero order, all three SES variables had high positive correlations with one another. Of the three, years of schooling completed had the lowest correlation with the others and the lowest correlation between 1960 and 1970 values. Years of schooling completed was the least persistent of the three variables over the decade.

Looking at the correlations as indicators of the stability of the suburban SES hierarchy, our comparison of Long Island communities in 1960 and 1970 shows a substantial degree of persistence. From one point of view, it can be said that these communities have a strong tendency to maintain their relative standings in the regional status hierarchy. Looked at another way, however, the coefficients may be regarded as measures of change rather than persistence. The relative positions of many of these communities in 1970 could not be predicted precisely from their positions in 1960. That the correlations are substantially less than 1.00 is an indication that there is some looseness in the system of stratification of suburban communities and that communities did experience upward and downward positional change.

Three Components of Change

In order to properly address the issue that has been raised concerning change vs. persistence, we need a statistic that will show the degree to which a char-

² Median income 1969 was corrected for inflation 1959-1969 by the factor 1/1.294 based on U.S. Department of Commerce estimates for the New York metropolitan region.

³ For these 12 cases, median family income was estimated by the regression of median family income on percentage of families with incomes over \$10,000 calculated for the other 77 cases. The correlation between the two income measures was found to be .94.

acteristic at a later point in time can be predicted from the same characteristic at an earlier point in time. Also, we require standardized measures of change in the mean of a variable and in its dispersion.⁴

Some of these requirements were met, or nearly met, by the measures of occupational mobility introduced by McClendon (1977). His work provides some of the basic logic for the development of our measures. Like McClendon's, our measures of persistence and change are derived algebraically by decomposing the sum of squared differences $\Sigma (Y-X)^2/N$. (In this and other equations, N represents N , $N-1$ or other appropriate degrees of freedom.) Here the previous value, X , is regarded as the "expected" value of Y , and $Y-X$ is the deviation of Y from the expected value. Thus, $\Sigma (Y-X)^2/N$ is a measure of dispersion of Y around the line $Y = X$. Each observation, X or Y , may be expressed as the mean plus a deviation from the mean. This deviation may be formulated as the product of a standard score times the standard deviation. The general definition of total change, then, is:

$$\Sigma(Y-X)^2/N = \Sigma[(\bar{Y} + Z_y s_y) - (\bar{X} + Z_x s_x)]^2/N. \quad (1)$$

Our approach in breaking this equation down into components is to solve for one component while assuming that the other two components are zero. For reasons that will be apparent in equation (4), all measures will be standardized by dividing by $2s_x^2$.

1. *Change of mean.* Assuming that there is no change in the relative positions of individuals in the distribution of Y as compared with their positions in the distribution of X , for each individual, $Z_y = Z_x$. If there has been no change of dispersion, $s_y = s_x$. Under these assumptions, equation (1), standardized by dividing by $2s_x^2$, becomes:

$$\begin{aligned} \text{Change of mean} \\ &= \Sigma(\bar{Y} - \bar{X})^2/2s_x^2 N \\ &= (\bar{Y} - \bar{X})^2/2s_x^2. \end{aligned} \quad (2)$$

⁴ Feldman (1972) recognized the three types of change discussed here. Increased dispersion, which he called *accentuation* is examined at length in Feldman and Weiler (1976).

2. *Change of dispersion.* If there is no change in the mean and if each individual's position as measured by Z remains unchanged, we may substitute \bar{X} for \bar{Y} in equation (1) and standardize by $2s_x^2$ to obtain:

$$\begin{aligned} \text{Change of dispersion} \\ &= \Sigma(Z_y s_y - Z_x s_x)^2/2s_x^2 N \\ &= \Sigma(Z_y^2 s_y^2 - 2Z_y Z_x s_y s_x \\ &\quad + Z_x^2 s_x^2)/2s_x^2 N; \end{aligned}$$

and since $\Sigma Z_y^2/N=1$ and $\Sigma Z_x^2/N=1$ and $\Sigma Z_y Z_x/N=r$, this simplifies to:

$$=(s_y^2 + s_x^2 - 2s_y s_x r_{yx})/2s_x^2.$$

When $r=1$, this becomes:

$$(s_y - s_x)^2/2s_x^2. \quad (3)$$

3. *Positional change.* If there is no change in the mean or standard deviation, the only change is in relative positions or Z scores. Substituting \bar{X} and \bar{Y} and s_x for s_y in equation (1) and subtracting, we obtain:

$$\begin{aligned} \text{Positional change}^5 \\ &= \Sigma(Z_y s_x - Z_x s_x)^2/2s_x^2 N \\ &= \Sigma(Z_y^2 s_x^2 - 2Z_y Z_x s_x^2 + Z_x^2 s_x^2)/2s_x^2 N \\ &= 1 - r_{yx}. \end{aligned} \quad (4)$$

Positional change is often referred to as the "regression effect," the tendency of individuals or successive generations on the average, over time, to fall back toward the mean. Graphically, it is a clockwise rotation of the regression slope, β_{yx} , away from the 45-degree line, $Y = X$.

4. *Combined effect of change of dispersion and positional change.* Up to this point the basic measures of change have been derived assuming that as each of the three components changes the other two are constant. In reality, of course, all three may change at the same time, and total change is the net result of their movements. Change of the mean has a simple additive effect which has no influence on the effects of the other two components. Once the effect of change of the mean has been taken out, however, the remaining change is partly the sum and

⁵ The term *positional change* was suggested by Duncan et al. (1961). McClendon (1977) adopted $1-r$ as his measure of exchange mobility.

partly the product of the other two components.

In the definition of definitional change, $1-r$, it was assumed that $s_y = s_x$. Any change from this equality produces a change in the effect of $1-r$, in the following manner:

$$\begin{aligned} \text{Combined effect} \\ = [2(s_y s_x - s_x^2)(1-r)]/2s_x^2. \end{aligned} \quad (5)$$

An increase in dispersion enlarges the effect of $1-r$ and a decrease diminishes it. Correspondingly, a change in $1-r$ heightens or reduces the effect of a change of dispersion.

5. *Total change.* Recombining the three components, the complete equation for change is:

$$\begin{aligned} & \frac{\Sigma(Y-X)^2/N}{2s_x^2} \\ &= \frac{(\bar{Y}-\bar{X})^2}{2s_x^2} + (1-r) + \frac{(s_y - s_x)^2}{2s_x^2} \\ &+ \frac{2(s_y s_x - s_x^2)(1-r)}{2s_x^2}. \end{aligned}$$

Regional Measures of Change and Persistence

The change and persistence measures for Long Island communities are summarized in Table 3. Comparing the three SES variables, we see that income had by far the highest coefficient of total change and occupational composition had the lowest. Change of the mean contributed over half of the change in education and income, and virtually nothing in occupation. Positional change accounted for nearly half of the change on the education dimension and most of the small amount of change in occupational status, but only a little more than 4% of the change in income. Change of dispersion was large only in the case of median family income, zero for occupation and negligible for education. Of the three variables, income has by far the highest coefficients of structural change.⁶

⁶ After some discussion we decided not to adjust the income figures beyond correcting them for inflation. Since SES is a relative matter, one may argue

Table 3. Components of Change of SES Characteristics for 89 Long Island Communities, 1960-1970

Component	Pct.		
	Median Years School	Upper White Collar	Median Family Income
a) Change of Mean $(\bar{Y}-\bar{X})^2/2s_x^2$.222	.016	1.368
b) Change of Dispersion $(s_y-s_x)^2/2s_x^2$.003	.000	.758
c) Positional Change $(1-r_{yx})$.217	.090	.102
d) Dispersion and Position $[2(s_y s_x - s_x^2)(1-r_{yx})]/2s_x^2$	-.020	.000	.126
2) Total Change*	.422	.107	2.354

* Sum of the components.

As a computation check, total change may be found either by directly computing

$$\frac{\Sigma(Y-X)^2/N}{2s_x^2}$$

from individual data or by calculating it from aggregate values by:

$$[(\bar{Y}-\bar{X})^2 + s_y^2 + s_x^2 - 2s_y s_x r]/2s_x^2.$$

Although the three indicators of SES are highly intercorrelated, they were evidently subject to different sets of influences during the 1960-1970 decade. Multiple regression analyses (see fn. 7) have shown that positive positional change of the educational level of suburbs is associated with high rates of population increase, little increase of occupational status and still less increase of income. Our explanation for this is that the adult male newcomers to rapidly growing suburbs were high in education, but being young, had not yet worked their way to upper status occupations or higher incomes.

Meanwhile, in both established and growing suburbs, the principle of consolidated advantages (or disadvantages) appears to be at work, widening the gap between rich and poor communities. While it

that the pursuit of SES is a zero-sum game and that in effect the increase of incomes represents inflation of the cost of SES. Under this interpretation the income figures for 1969 should be further corrected by an "SES inflation factor." The issue of how to obtain this factor is too complex to explore in this paper.

is clear that cost of home ownership is the primary mechanism for selection into the exclusive suburbs or gravitation to the poorer communities, it is not clear to us why the suburbs did not become increasingly differentiated on occupation and education as well as income. A clearer perception of the relations between the three dimensions of SES must await comparative analyses of different regions and time periods. The patterns of widening income inequality along with narrowing educational inequality may be unique to a certain stage of development of a suburban region, or to the 1960–1970 decade or to a particular type of economic or political structure. These questions can only be confronted adequately in comparative studies.

With the full display of components of persistence and change in Table 3, it can be seen that attention to persistence alone, as represented by r , leads to an incomplete description of trends over time. Moreover, persistence has been taken to imply lack of any kind of change. As we have shown, there are other kinds of change that are mathematically independent of the correlation coefficient. An increase in the dispersion, as in income, is a change in the range of differences between suburbs that has significant sociological implications. An increase of the mean, as in education and income, signifies that most communities experienced a gain in status at least in the absolute sense if not in relation to other communities. The positional change coefficients reveal that there were significant changes in the relative SES positions of many suburbs.⁷

⁷ Checking against the possibility that positional change may result from measurement errors and chance fluctuations, we treated each of the three SES measures for 1970 as the dependent variable in a multiple regression analysis, and introduced its 1960 value as the first independent variable. The remaining variance to be accounted for is positional change. The analysis showed significant and systematic effects of variables that, on theoretical grounds, are expected to influence positional change. Consistent with previous studies by Farley (1964) and Guest (1974; 1978), we found that population growth strongly affected change of relative standing in the level of education ($\beta = .296$). Growth had a lesser effect on the percentages of males in upper white-collar occupations ($\beta = .167$) and still less of an

Conclusions

An empirical examination of the three different approaches to the study of suburban change and persistence lends support to each of them. Positional change, change of dispersion and change of the mean are all important components. Simultaneous measurement of all three components yields a more complete description of intertemporal differences than can be provided by any one perspective alone.

Apparent inconsistencies between different theories of suburban development as well as discrepancies between empirical findings and theory can be resolved by separately measuring the three distinct dimensions of change. All models require persistence, for the suburban region is after all a system with a structure and with strong patterns of functional interdependence between its component parts. Some models lead us to expect positional change in status under the influence of population growth and other factors. The aggregate effect of such changes is appropriately measured by the positional change coefficient, and the determinants of positional change may be investigated by multiple regression. Other models, including the concentric zone model under certain assumptions, predict a gradual change in the mean of an SES characteristic over time. Still others may lead us to expect a decrease or increase of the range of differences between suburbs. The consequences for change in each of the three dimensions should be explicitly stated for each theoretical model, and each change hypothesis should be tested with the use of the appropriate change measure.

Mainly because of a lack of comparable data, previous analyses of positional change in suburban SES have looked at only one SES characteristic, namely, education. Here, we have examined change and persistence of three indicators of

effect on median family income ($\beta = .086$). Our interpretation is that the newcomers to rapidly growing suburbs were high in education, but being young, had not yet worked their way to upper status occupations or higher incomes. Distance from the central city, age of housing and incorporation all had significant effects on positional change of one or more of the SES indicators.

SES: education, occupation and income. It is interesting that in spite of the high intercorrelations among these three variables in 1960 and again in 1970, there is a great deal of variation in patterns of change of these different aspects of socioeconomic status. Positional change was lowest for the occupational dimension and highest for the educational dimension. Structural changes in both mean and dispersion were highest for income and lowest for occupation. These differences alert us to the possibility that studies using only one indicator of SES may obtain different results depending on which SES variable is analyzed. Thus we propose that multiple indicators of SES should be employed where possible and that results obtained with only one indicator, such as education, should be interpreted with caution.

The standardized change measures developed here will facilitate comparisons not only between different indicators of a concept such as SES but also between regions or other groupings and between different time periods. They provide a way to summarize, for comparative purposes, very complex patterns of change within a region or other grouping. Yet they are easy to calculate, requiring only the before-after correlation of a variable, and its mean and standard deviation at the beginning and again at the end of the time interval under study.

It is our hope that the method will contribute to the clarification and more accurate testing of the theoretical models through which we seek to understand the workings of social systems.

INCOME INEQUALITY: A CROSS-NATIONAL STUDY OF THE RELATIONSHIPS BETWEEN MNC-PENETRATION, DIMENSIONS OF THE POWER STRUCTURE AND INCOME DISTRIBUTION*

VOLKER BORNSCHIER AND THANH-HUYEN BALLMER-CAO

University of Zurich

American Sociological Review 1979, Vol. 44 (June):487-506

We see personal income inequality as a function of the distribution of power. In contrast to most of the previous research in this field three dimensions of power distribution within countries are explicitly taken into account: the organizational power distribution, the distribution of power in the labor market, and the "steering power" of the state. Going beyond previous formulations of a power theory of income inequality, we take explicitly into account the embracing system of the world economy. The specific focus is on the institution of the multinational corporation (MNC) which forms an all-embracing structure linking countries in a differential manner to the world economy. The concepts of MNC-headquarter status and MNC-penetration are introduced. With respect to the latter, we test the hypothesis that the extent of MNC-penetration affects power distribution which in turn results in a more unequal pattern of income distribution. Empirical analysis is based on multiple regression and pathanalysis. Although no empirical evidence is found to support the complementary hypothesis, i.e., that MNC-headquarter status leads to greater income equality, the hypothesis with regard to MNC-penetration does receive empirical support. Significant positive effects of MNC-penetration on income inequality are demonstrated via its relationship to all three dimensions of the power distribution. Directions for further research are suggested.

INTRODUCTION

Income inequality long has been thought to be an important aspect of social inequality. Several attempts at an empirical cross-national explanation of income inequality have been presented in this journal in recent years (Cutright, 1967; Jackman, 1974; Chase-Dunn, 1975; Robinson, 1976; Hewitt, 1977; Robinson
